CHAPTER OUTLINE

FUNCTIONAL GENETICS OF CHILDHOOD CANCER PREDISPOSITION SYNDROMES
DYSREGULATION OF CELL DIVISION AND GROWTH
DNA REPAIR AND GENOME INSTABILITY
ABERRANT GENE EXPRESSION
SOMATICALLY ACQUIRED GENE MUTATIONS AND CANCER GENOMICS
GENOMIC REARRANGEMENTS AND CHROMOTHRIPSIS
DNA METHYLATION, CHROMATIN, AND THE EPIGENETICS OF CHILDHOOD CANCER
DNA METHYLATION
CHROMATIN-MODIFYING ENZYMES
SPLICING FACTORS
METABOLIC ENZYMES
CONCLUSIONS AND FUTURE OUTLOOK

The first scientific reports of childhood cancers such as Virchow glioma (neuroblastoma), Wilms tumor (nephroblastoma), and Ewing sarcoma provided a classification system based on organ involvement but shed little light on the natural causes of these diseases. Subsequent study of cancer cells and animal tumors, and in particular Boveri's analysis of cell mitoses and Rous' study of oncogenic viruses, revealed that cancer is at least in part a disease of genes and their aberrations.[1,2]

With the advent of molecular biology, we learned that animal oncogenic viruses contain mutant versions of cellular genes, termed *oncogenes*, as well as gene products that negatively regulate endogenous tumor suppressor genes.[3] Expressed in normal cells, these tumorigenic viral genes can cause unrestrained proliferation and, ultimately, immortalization and malignant transformation, leading to the concept that human cancer is caused by the dysregulation of endogenous protooncogenes and tumor suppressor genes.[4-6]

In particular, the idea of endogenous tumor suppressor gene inactivation in human cancers is strongly supported by (1) the analysis of the age dependence of retinoblastoma incidence and (2) the finding that in children who inherit one mutant allele, bilateral tumors develop at an earlier age than in persons who have tumors that develop as a result of spontaneous biallelic inactivation.[6] Although this "two-hit" model provides a powerful explanation of the incidence of retinoblastomas, similar analyses of other human cancers led to the conclusion that at least six different genetic mutations are needed to explain the apparent age-dependent incidence of some human tumors.[7,8] Indeed, a large majority of human cancers contain many gene mutations in a complex clonal architecture, as revealed by recent analysis of tumor genomes by next-generation sequencing. Some tumors, however—particularly those in children—can have surprisingly low mutation rates. Finally, even cancers with extremely low numbers of gene mutations contain mutations outside of genes that could contribute to tumorigenesis. Consequently, the extent to which alterations in noncoding genetic elements and epigenetic changes have the potential to cooperate with or substitute for genetic mutations has become an active area of investigation.

In addition to the polygenic nature of human cancers, many features of tumor cells are not directly explained by the mutation of cancer-causing genes but instead involve complex cell and tissue biologic systems. These "hallmarks of cancer," which include limitless cell replication, self-sufficiency in growth signaling, circumvention of cell death, immune system evasion, and the ability to metastasize, provide an expedient phenomenologic model to understand cancer cell behavior.[9,10]

Recently, contributions from changes in the chemical modifications of deoxyribonucleic acid (DNA) and chromatin have been increasingly implicated in cancer pathogenesis. These changes are often referred to as "epigenetic" because they may have the potential to result in somatically heritable changes in gene expression and phenotype that do not result directly from changes in DNA composition. Normal development provides a vivid illustration of the power of epigenetic changes, because virtually every cell in the body contains mostly identical coding DNA sequences and yet cells display markedly different behaviors and fates. For example, mature neurons have a distinct differentiated appearance and never divide, whereas hematopoietic stem cells divide throughout a person's lifetime. Further, these cellular fates remain stable over years of somatic cell division. Given the role of epigenetic regulation in the control of cell fate, perhaps it is not surprising that epigenetic perturbations may also contribute to oncogenesis. Although they are conceptually distinct, genetic and epigenetic dysregulation can be closely associated in cancer cells, while genetic mutations of epigenetic regulators are increasingly recognized, particularly in childhood tumors.

Whereas somatic cancer mutations are relatively easy to identify by comparing the sequence of DNA between tumor and nontumor cells, epigenetic causes of cancer are much more difficult to discern because the normal epigenetic state varies with cell type, which makes defining aberrant features a challenge. With respect to DNA methylation, it has become evident that cancer genomes overall tend to be hypomethylated compared with normal tissues and that they have focal areas of hypermethylation in the promoters of specific genes associated with silencing of gene expression. Similarly, the recent discovery of mutations in genes that regulate chromatin structure suggests that aberrant chromatin modifications may contribute to tumorigenesis via epigenetic dysregulation rather than through the induction of additional genetic mutations, although in most cases this conjecture has yet to be proven.

Arguably, our ability to decipher the biologic basis of human cancer will depend on understanding the relationship between molecular aberrations and dysregulated properties of cancer cells. Awareness of the importance of this problem is increasing in the field of pediatric oncology, leading to the recognition that although some childhood tumors can have a remarkably low number of recurrently mutated genes, others can contain thousands of DNA substitutions and complex chromosomal rearrangements. Pediatric cancers may be conceptually distinct from those that occur in adults, because in the absence of a syndromic predisposition, children otherwise have relatively low rates of somatic genetic alterations and toxin exposures due to aging. Thus childhood cancers may involve unique mechanisms of tumorigenesis.

In this chapter we review the mechanisms of molecular pathogenesis of childhood cancers. Our goal is not to provide a comprehensive encyclopedia (electronic publishing and online databases* now enable ready access to this information) but to develop a systematic classification of the molecular lesions responsible for childhood tumors, with a focus on biologic mechanisms and functional principles. Instead of organizing this chapter on the basis of cancer types, which are covered individually in other chapters of this volume, we have attempted to develop a functional framework that we hope will provide helpful insights into the relationship between molecular aberrations and behaviors of cancer cells *sui generis*. Such an approach should inform the development of improved clinical therapies, particularly if cancer treatment is to become more precise through the use of rationally targeted agents.

FUNCTIONAL GENETICS OF CHILDHOOD CANCER PREDISPOSITION SYNDROMES

The study of childhood cancer predisposition syndromes is an important source of information about the genetic basis of human cancers. Indeed, the retinoblastoma 1 *(RB1)* gene, which is mutated in familial retinoblastomas, was the first human tumor suppressor gene identified.[6,11,12] What follows is an overview of known genes mutated in childhood cancer predisposition syndromes based on the major cell biologic pathways thought to be perturbed by the inherited gene mutations.

DYSREGULATION OF CELL DIVISION AND GROWTH

A large number of childhood cancer predisposition syndromes involve mutations of genes that regulate cell growth and division. One of the first to be described, the *RB1* gene, is mutated in children who are predisposed to the development of retinoblastoma, pinealoblastoma, and osteosarcoma. The *RB1* gene is part of the G1 cell cycle checkpoint, where its product directly binds and regulates the activity of the E2F family of transcription factors and the DREAM chromatin remodeling complex in response to stress.[13] Cancer-causing deletions and nonsense mutations of *RB1* can cause entry into the cell cycle by otherwise quiescent cells and mitigation of senescence that limits cellular life span.[14] Whereas loss of *RB1* in cellular and mouse models causes defects in mitotic chromosome segregation that lead to aneuploidy,[15,16] most human retinoblastomas are largely diploid,[17] suggesting that the canonic chromosome segregation effects of *RB1* inactivation in human retinoblasts are functionally compensated. Human retinoblastomas invariably exhibit biallelic inactivation of *RB1*, but otherwise often have a comparatively low mutation rate. One study found that *RB1* was the only known cancer gene mutated in these tumors.[17] However, additional subclonal DNA mutations were observed, with some mutations located outside of coding regions, which may cooperate with *RB1* loss to drive retinoblastoma formation. In addition, epigenetic alterations have also been implicated in cooperating with *RB1* mutation.[17]

The adenomatous polyposis coli *(APC)* gene, which is mutated in children with familial adenomatous polyposis who are predisposed to hepatoblastoma and colon carcinoma, also controls the G1 cell cycle checkpoint.[18] APC serves as a ubiquitin ligase that regulates the protein stability of β-catenin, which controls transcription of cyclins, including cyclin D, which in turn associates with cyclin-dependent kinase (CDK)4/6 to negatively regulate *RB1* activity.[19] Disease-associated dominant mutations of *APC* tend to occur in distinct regions of the gene, leading to the generation of truncated protein products, consistent with the requirement of residual or neomorphic activity of the mutant proteins.[20] Because *APC* regulates the stability of many proteins—and because, in addition to the cell cycle progression, β-catenin also regulates cell adhesion and differentiation—the mechanism of tumorigenesis induced by *APC* mutations is thought to be pleiotropic.

---

*At the time of this writing, the following publicly accessible databases of cancer-associated mutations and structural aberrations are available: http://target.cancer.gov; http://pediatriccancergenomeproject.org; http://www.sanger.ac.uk/genetics/CGP; and http://cansar.icr.ac.uk.

In addition to mutations of genes whose products regulate cell division, cancer-causing mutations also directly dysregulate mitogenic signaling and cell growth. The most common cancer predisposition syndrome, neurofibromatosis, is predominantly caused by autosomal-dominant inheritance of inactivating mutations of the neurofibromin 1 *(NF1)* gene, with the less frequent form caused by mutations of neurofibromin 2 *(NF2)* or *merlin*. Children with mutations of *NF1* are predisposed to the development of benign and malignant tumors, including gliomas, peripheral nerve sheath tumors, pheochromocytomas, and leukemias.[21] NF1 is a large protein that is not completely understood but is known to regulate the activity of rat sarcoma (Ras).[22,23] In turn, *NF1* mutant tumors exhibit increased Ras guanosine triphosphate hydrolase activity, which stimulates the mitogen-activated protein and AKT kinase cascades that, among other effects, result in the transcription of genes involved in cell growth and stimulation of protein synthesis.[24-26] Although most patients with germline *NF1* mutations experience the development of neurofibromas, which harbor biallelic inactivation of the gene, only a minority of these tumors evolve to become malignant. This finding indicates that disease-associated *NF1* mutations have limited transforming ability, and that additional lesions are required for carcinogenesis.

The complex relationship between cancer-causing gene mutations and their effects on tumorigenesis is also evident from mutations of *ras* genes themselves. Genes related to *ras*, including Kirsten rat sarcoma *(KRAS)*, neuroblastoma rat sarcoma (*NRAS)*, and Harvey rat sarcoma *(HRAS)*, are some of the first human protooncogenes identified, based on the involvement of the corresponding viral oncogenes in the pathogenesis of rat sarcomas.[27] However, whereas *NF1* mutations stimulate Ras activity and cause neurofibromatosis, patients with inherited mutations of the *ras* genes instead experience the development of cardiofaciocutaneous, Noonan, LEOPARD, and Costello syndromes. Inherited mutations of the *ras* genes are missense activating mutations, analogous to the oncogenic viral *ras* mutations, yet the spectrum of tumor phenotypes in these patients is distinct. In addition to gliomas these phenotypes also include leukemias, neuroblastomas, and rhabdomyosarcomas.[28,29] These differences between *NF1*- and *ras*-mutant cancer predisposition syndromes are not simply due to differences in tissue expression of the two genes, because both appear to be expressed in neuronal, mesenchymal, and hematopoietic tissues. Rather, they may reflect the developmental consequences of Ras activation as a result of the inactivation of an endogenous negative regulator as opposed to direct mutational activation of an oncogenic signaling pathway, a property that may inform the development of strategies to target these lesions therapeutically.

DNA REPAIR AND GENOME INSTABILITY

The prevention of de novo cancer-causing mutations ultimately depends on efficient DNA repair and maintenance of genome stability. Indeed, several cancer predisposition syndromes involve defective DNA repair. For example, inherited mutations of the tumor protein 53 (*TP53)* tumor suppressor gene cause most cases of Li-Fraumeni syndrome, which is associated with the predisposition to sarcomas, leukemias, and breast carcinomas.[30] The genotype-phenotype relationship of *TP53* cancer-causing mutations is complex, with some mutations having apparent loss-of-function, dominant-negative, or gain-of-function properties in experimental models.[31-34] p53 regulates the expression of genes involved in cell division, apoptosis, and DNA repair, and its mutation in cells leads to chromosomal instability.[35,36] This process is mediated partly by direct effects of p53 on the transcription and translation of target genes, as well as via feedback interaction with its ubiquitin ligase murine double minute 2 (MDM2), which also has oncogenic effects independent of its negative regulation of p53.[37] As a result, the dysregulation of cellular DNA damage and stress response by *TP53* mutations is profoundly tumorigenic, contributing to the somatic pathogenesis of most human cancers. The p53-MDM2 feedback regulation also complicates therapeutic targeting, because inhibition of MDM2 aimed at restoring p53 tumor suppression may in effect enhance the deleterious activity of gain-of-function p53 mutant proteins.[38]

Defective DNA damage response is also a hallmark of Fanconi anemia (FA), a cancer predisposition syndrome characterized by bone marrow failure and development of myelodysplasia, leukemia, and carcinomas.[39,40] Although mutations of more than 15 different genes can cause FA, most of the known FA-mutant gene products physically interact with the components of a conserved DNA damage response mechanism, breast cancer 1 (BRCA1), ataxia telangiectasia mutated (ATM), Nijmegen breakage syndrome 1 (NBS1), and radiation-sensitive 51 (RAD51), and are required for the repair of chromosome defects that occur during homologous recombination.[39] FA pathway–deficient cells are hypersensitive to DNA-damaging agents, and over time they accumulate deleterious gene mutations (usually segmental deletions).[41]

Several other chromosome-breakage syndromes with cancer predisposition involve defects in closely related biochemical pathways of DNA repair of homologous recombination errors, such as ataxia telangiectasia (due to mutations of *ATM*), Nijmegen breakage syndrome (due to mutations of *NBS1*), and Bloom syndrome (due to mutations of *BLM*). Genes involved in nucleotide excision or transcription-coupled DNA repair can also be mutated and cause the cancer predisposition syndromes xeroderma pigmentosum and Cockayne syndrome, usually due to accumulation of ultraviolet radiation–induced mutations (typically nucleotide substitutions).[42]

ABERRANT GENE EXPRESSION

Another hallmark of cancer cells is expression of genes in inappropriate developmental states, often driven by mutations of gene products that regulate gene expression. For example, patients with inherited mutations of the Wilms tumor 1 *(WT1)* gene experience development of the Denys-Drash syndrome (due to loss-of-function missense mutations) or the Wilms tumor, aniridia, genitourinary anomalies, and mental retardation (WAGR) syndrome (due to gene deletions), both with predisposition to the development of bilateral Wilms tumors.[43] In spite of years of study, the function of the WT1 protein is incompletely understood. WT1 is a key regulator of mesenchymal cell development, including kidney mesenchyme, in part through its functions as a transcriptional repressor.[44] However, WT1 also interacts with messenger RNA (mRNA) and splicing factors, consistent with possible posttranscriptional functions in regulation of gene expression.[45] In addition, although recessive mutations of *WT1* appear consistent with its tumor suppressive functions in Wilms tumorigenesis, in other developmental and tissue contexts, particularly myeloid leukemias, WT1 can enhance cell survival and proliferation and as a result can act as an oncogene or haploinsufficient tumor suppressor gene.[46] Such tissue-dependent phenotypes are characteristic of cancer-associated genes that affect gene expression and cell fate determination, insofar as the functional consequences of mutations depend on the spectrum of expressed genes themselves and differentiation state in general.

Tumorigenesis due to aberrant regulation of gene expression can also occur posttranscriptionally, as in the case of inherited mutations of the *DICER1* gene, which predispose to the development of pleuropulmonary blastoma, cystic nephroma, and rhabdomyosarcoma.[47] *DICER1* is a ribonuclease that is required for the generation of endogenous microRNAs (miRNAs), which negatively regulate gene expression by inducing degradation and translational blockade of specific mRNAs.[48] Cancer-associated mutations affect conserved, enzymatically required residues in *DICER1* and cause defective miRNA processing, leading to increased expression of target genes.[49] The reason inherited *DICER1* mutations predispose specifically to the development of pleuropulmonary blastoma, cystic nephroma, and rhabdomyosarcoma is not understood, but it is reasonable to hypothesize that this predisposition is due to the specific requirements for miRNA-mediated gene expression in these tissues or expression of specific target protooncogenes.

SOMATICALLY ACQUIRED GENE MUTATIONS AND CANCER GENOMICS

Many cancer-causing gene mutations that are inherited as part of familial cancer predisposition syndromes can also be acquired somatically in tumor cells. These mutations include most of the genes described in the preceding sections, but with notable differences in pathogenic mechanisms.

First, in many instances of somatic mutations of tumor suppressor genes, only one of the alleles is mutated, leaving the other wild-type allele intact and expressed.[50] Such haploinsufficient mutations, as opposed to the classic "two-hit" tumor suppressor gene mutations, are thought to exert their effects through reduced tumor suppressive activities as part of tumor initiation. In addition, the functional contributions of the wild-type allele may be required for tumor maintenance in some cases. This distinction may be crucial for the development of therapeutic strategies to target haploinsufficient tumor suppressors, because restoration of tumor suppressor gene functions may be not be useful in tumors in which residual wild-type activity is required for tumor maintenance.[51]

Second, the tumor spectrum and phenotype, and therefore the exact mechanism of tumorigenesis, are often different for the same mutation when it is developed somatically as opposed to inherited in the germline. For example, inherited mutations of *WT1* cause Denys-Drash syndrome and predisposition to Wilms tumors but never leukemias, whereas somatic mutations of *WT1* occur in 10% of cases of acute myeloid and T-cell acute lymphoblastic leukemias (ALLs).[52] This difference may be due to the differences in gene expression and differentiation state of cells that are transformed by these tumorigenic mutations. The same principle is likely responsible for the nonequivalence of many other somatically acquired tumor mutations that have counterparts that occur as part of inherited developmental syndromes, such as the loss-of-function mutations of BCL6 corepressor *(BCOR)* that occur somatically in medulloblastomas and myeloid leukemias but cause oculofaciocardiodental syndrome without cancer predisposition when inherited in the germline.[53-55]

Finally, recent whole-genome surveys have revealed that recurrence rates of somatically acquired gene mutations may be rare when considered individually but can involve coherent biologic pathways that are mutated frequently as a functional group. This functional co-occurrence is often suggested by the mutual exclusivity of the individual mutations. We review the mechanisms of tumorigenesis by these mutations, as organized below by shared biochemical activities or biologic pathways.

GENOMIC REARRANGEMENTS AND CHROMOTHRIPSIS

Structural genomic rearrangements and copy number changes are particularly prevalent in adult cancers, both at the level of whole chromosomes and chromosomal segments, particularly in advanced or histologically anaplastic diseases, but they are generally somewhat less prominent in pediatric cancers. The mechanisms of their generation and tumorigenic sequelae at least in part appear to be related to the dysfunction of DNA repair and maintenance of genome stability. In particular, whole chromosome aneuploidy, often as a result of chromosomal instability due to defects in mitosis such as centrosome amplification or failure of spindle assembly, is a prevalent feature of anaplastic tumors.[56] In some cases, such as acute myeloid leukemias, mutations of the components of the mitotic cohesin complex, including stromal antigen 2 (STAG2), structural maintenance of chromosomes 3 and 1A (SMC3 and SMC1A), and radiation-sensitive 21 (RAD21), may lead to chromatin cohesion defects and aneuploidy.[57] However, identification of such cohesin complex mutations in karyotypically normal acute myeloid leukemia (AML) raises the possibility that their tumorigenic effects rely on nonmitotic functions of the cohesin complex components.[58]

In model systems, aneuploid cells appear to have increased rates of mutation and susceptibility to DNA damage.[59,60] Noncancerous aneuploid human cells tend to be nonviable, with the exception of cells with trisomies of chromosomes 13, 18, and 21 and certain ring chromosomes.[61] However, somatically acquired chromosomal aneuploidy is far more prevalent in tumors than in constitutional syndromes, suggesting that additional molecular changes that enable tumor cells to tolerate aneuploidy must exist. Indeed, tumors with characteristic aneuploidies often have specific additional mutations—for example, overexpression and mutational activation of cytokine receptor-like factor 2 (CRLF2) signaling in B-cell ALL (B-ALL) with trisomy of chromosome 21.[62-64] Defining the molecular basis of these interactions may reveal potential opportunities to therapeutically target mechanisms that permit tolerance of aneuploidy in cancer cells.[65]

One of the best-studied genomic aberrations in cancer cells is recurrent chromosomal translocations. These chromosomal rearrangements generally lead either to the aberrant expression of protooncogenes as a result of juxtaposition of regulatory transcriptional elements or to the generation of chimeric fusion gene products that have gain-of-function tumorigenic effects.[66] Chromosomal translocations are frequently observed in hematopoietic cancer cells, where they lead to increased survival, growth, and malignant transformation, such as MYC-overexpressing t(8;14) translocation in Burkitt lymphomas and t(9;22) translocation generating the BCR-ABL1 fusion proteins in B-ALL and chronic myeloid leukemia. In lymphoid cells, these translocations are generated at least in part by aberrant V(D)J recombination and activation-induced deaminase activities that occur at the immunoglobulin and T-cell receptor loci undergoing somatic hypermutation. In addition, recombination of endogenous repetitive elements and DNA topoisomerase II failures also appear to cause chromosomal translocations, such as those generating mixed-lineage leukemia (MLL) fusion proteins.[67,68]

The chimeric fusion proteins generated by these translocations have been found to disrupt cell differentiation and specification, along with enhanced cell survival and growth.[69] For example, the TEL-AML1 fusion protein leads to abnormal self-renewal of hematopoietic stem cells, making them susceptible to additional mutations and ultimate transformation to B-ALL.[70,71] The EWS-FLI1 fusion protein in Ewing sarcoma disrupts specification of mesenchymal progenitors, blocking cell differentiation.[72-74]

By virtue of being tumor-specific, fusion gene products generated by chromosomal translocations represent attractive targets for rational therapy. Indeed, introduction of all-*trans*-retinoic acid and arsenic trioxide to induce the degradation of the chimeric PML-RARA fusion protein caused by the t(15;17) chromosomal translocation in the majority of cases of acute promyelocytic leukemia has revolutionized the treatment of this disease by eliminating the need for chemotherapy.[75]

In addition to the gains and losses of whole chromosomes and their segments, cancer cells can exhibit other distinct and complex types of genomic rearrangements. In particular, some tumors such as neuroblastomas and gliomas, for example, have been found to contain short episomal DNA fragments, termed *double minutes,* that lack centromeres and telomeres.[76,77] In neuroblastomas, these double minutes contain multiple copies of the *MYCN* protooncogene, leading to its high-copy amplification and overexpression. The mechanisms generating these episomal DNA fragments are not well defined but may involve recombination or transposition events involving endogenous *Alu, LINE*, and *MER* elements, or microhomology-based aberrant nonhomologous end-joining reactions.[77]

Recently a highly complex form of genomic rearrangements, termed *chromothripsis*, has been described in a variety of tumors, including neuroblastomas, medulloblastomas, and osteosarcomas.[78-80] This phenomenon is defined by extensive intrachromosomal rearrangements, often numbering in the thousands, of a single chromosome.[81] It has been proposed to be caused by aberrant DNA replication and microhomology-based nonhomologous end-joining repair, as well as by damage of chromosomes trapped in micronuclei as a result of mitotic errors.[80,82,83] The mechanisms of the generation of these complex rearrangements and their functional consequences remain to be defined but promise to reveal important insights into the mechanisms of human tumorigenesis, given their marked prevalence in distinct tumor types.

DNA METHYLATION, CHROMATIN, AND THE EPIGENETICS OF CHILDHOOD CANCER

Structural abnormalities in the genomes of cancer cells seem essential for tumorigenesis, but increasingly, the contribution of aberrant epigenetic regulation to the development of human cancers in general and pediatric cancers in particular is also becoming recognized. Methylation of cytosines in DNA can cause profound changes in transcription, and methylation of CpG islands in the promoters of genes can lead to transcriptional silencing.[84,85] In addition, nuclear DNA is tightly bound to histones as part of chromatin, and sequence-specific posttranslational modification of histones, including acetylation, methylation, and ubiquitination, have all been shown to modulate DNA accessibility and transcription.[86,87] Consequently, the transcription of individual genes depends both on the degree of DNA compaction and accessibility, as well as on the individual chemical modifications of histones surrounding specific genes.

DNA METHYLATION

Methylation of cytosines in DNA is a key regulator of mammalian cell development, and changes in DNA methylation have long been known to be associated with human cancer. For example, loss of normal DNA methylcytosine imprinting patterns on chromosome 11 causes Beckwith-Wiedemann syndrome, a developmental disorder that predisposes to the formation of hepatoblastomas and Wilms tumors.[88] Indeed, abnormal patterns of cytosine methylation are frequently observed in tumor cells, and recently mutations of enzymes that control DNA methylation have been found in AML and myelodysplastic syndromes.

The de novo DNA methyltransferase 3A (DNMT3A) is recurrently mutated in a large fraction of cases of AML.[89,90] The mutations tend to be missense and heterozygous, involving an evolutionarily conserved DNA-binding interface of DNMT3A, consistent with a possible gain-of-function effect that presumably alters locus-specific DNA methylation. Loss-of-function deletions and nonsense mutations of methylcytosine dioxygenase 2 *(TET2)* are also observed in AML and myelodysplastic syndromes.[91-93] TET2 functions by hydroxylating methylcytosine, and these mutations are thought to lead to the loss of DNA hydroxymethylcytosine, although whether this is carcinogenic in itself or transforms cells indirectly via its effects on histone modifications and DNA demethylation remains to be determined.[94,95] Consistent with this notion, the CpG island methylator phenotype, which is a key factor in the tumorigenesis of adult colorectal carcinomas, is yet to be definitively established in tumors with defects in DNA methylation.[96]

CHROMATIN-MODIFYING ENZYMES

Whereas perturbation of nuclear appearance in cancer cells was long ago realized to represent a change in chromatin structure, the molecular underpinnings of this phenomenon have begun to be elucidated only recently. Perhaps the strongest evidence implicating perturbation of chromatin structure in carcinogenesis is the finding that chromatin-remodeling complexes are mutated at a high frequency in a wide variety of cancers. Some of these include genes that encode proteins that contribute to the methylation and acetylation of histone lysines. Others include those that encode subunits of complexes that mobilize histones and remodel chromatin structure. Numerous other modifications of histones also occur, such as arginylation, succinylation, and glycosylation, but their significance is only beginning to be assessed.

One of the earliest genes involved in chromatin modification that was identified as being mutated in pediatric cancers is the *MLLT1* gene, which contains the SET lysine N-methyltransferase domain that is characteristically lost as a result of chromosomal translocations that generate chimeric MLL fusion proteins in infant and topoisomerase inhibitor–induced leukemias.[97,98] Wild-type MLL and mutant MLL fusion proteins physically interact with a large supramolecular complex involved in regulation of gene expression by chromatin modification.[99] MLL fusion–induced leukemias are characterized by unique patterns of gene expression associated with a distinct spectrum of chromatin modifications, particularly those involving methylation of lysine 79 of histone 3 (H3K79), which in turn is associated with high levels of gene expression.[100] Notably, these activities require the preferential recruitment of the DOT1L lysine methyltransferase by the MLL fusion proteins compared with wild-type MLL, and DOT1L activity is required for leukemogenesis in preclinical models, potentially offering a therapeutic strategy.[101,102] Aberrant methylation of H3K79 at target genes of the MLL fusion protein therefore likely contributes to *MLLT1* translocation-induced leukemogenesis.

Whereas increased target gene H3K79 methylation by aberrant recruitment of a lysine methyltransferase represents a gain-of-function of tumorigenic methyltranferase activity, loss-of-function mutations of lysine methyltransferases have also been observed in tumors. In particular, loss-of-function frameshift and nonsense mutations of the suppressor of zeste 12 homologue *(SUZ12)*, embryonic ectoderm development *(EED)*, and enhancer of zeste homologue 2 *(EZH2)* genes are frequently found in T-cell ALL (T-ALL).[103,104] Similar mutations have also been observed in cases of myelodysplastic syndromes.[105,106] These gene products are physical components of the Polycomb repressive complex (PRC) 2, which methylates lysine 27 of histone 3 (H3K27), a modification associated with silencing of target gene expression.[107] It is important to note that whereas *EZH2* undergoes loss-of-function mutations in T-ALL, gain-of-function missense mutations of *EZH2*, which are associated with neomorphic enzymatic activity of the mutant protein, are observed in cases of diffuse large B-cell lymphoma.[108] The complexity of the tumorigenic mechanism of these mutations is further emphasized by the recent finding of loss-of-function mutations of the H3K27 demethylase *UTX*, which, when mutated, ought to potentiate H3K27 methylation in some cases of B-ALL.[109] The importance of regulation of H3K27 modifications was recently further highlighted by the finding that H3K27 itself is frequently mutated in pediatric diffuse pontine gliomas, in which lysine to methionine mutations occur in histone 3.3 or 3.1[110,111] and result in inhibition of PRC2.[112] Collectively, these findings indicate that the developmental and epigenetic state of the cell likely makes key contributions to tumorigenesis by the mutant chromatin-modifying enzymes by providing specific substrates for their altered enzymatic activities.

The recognized role of chromatin modifiers has continued to expand via cancer genome sequencing efforts and has led to identification of the switch/sucrose nonfermentable (SWI/SNF) chromatin remodeling complex as the most frequently mutated chromatin regulatory complex. Genes that encode subunits of this complex are mutant in 20% of all human cancers.[113] This 12- to 15-protein complex serves important roles in transcriptional regulation by utilizing adenosine triphosphate hydrolysis to modulate chromatin structure at the promoters and enhancers of its target genes. Identification of biallelic inactivating mutations of *SNF5/INI1/SMARCB1*, a core SWI/SNF subunit, in nearly all cases of malignant rhabdoid tumors represented the first identified link between an adenosine triphosphate–dependent chromatin remodeler and cancer.[114,115] Heterozygous *SMARCB1* mutation was also identified as the basis of a familial cancer predisposition syndrome.[114] Other SWI/SNF subunits have also recently been found to be recurrently mutated in pediatric malignancies, including *ARID1A* in Burkitt lymphoma, *ARID1A* and *ARID1B* in neuroblastoma, and *ARID1A* and *SMARCA4* in medulloblastoma. Although these findings broadly implicate the SWI/SNF complex in tumor suppression, the mechanisms by which these mutations drive cancer formation remain unclear.

The complex serves roles in transcriptional regulation by modulating the chromatin landscape at promoters and enhancers of its target genes; in addition, the complex has also been implicated in DNA repair.[116-121] However, recent sequencing of rhabdoid tumor genomes indicates that these cancers contain a remarkably simple protein coding genome, with mutations of *SMARCB1* essentially the sole recurrent genetic mutation; in some cases it is sole coding sequence mutation identified.[122-124] These findings have been interpreted as suggesting that oncogenesis caused by the mutation of the SWI/SNF complex occurs not via induction of genomic instability but rather via epigenetic dysfunction.[125] Perhaps providing mechanistic insight, mutation of *SMARCB1* was reported to result in unbalanced epigenetic antagonism between the SWI/SNF and PRC2 complexes, generating a unique dependence upon EZH2.[126] Preclinical small molecule inhibition of EZH2 has been reported to be effective against rhabdoid tumors in preclinical models but has yet to be tested in humans.[127]

Cancer genome sequencing has also identified other chromatin remodelers mutated in cancer. For instance, alpha-thalassemia mental retardation syndrome, X-linked *(ATRX)* and death-domain associated protein *(DAXX)*, which encode subunits of a chromatin-remodeling complex required for replication-independent deposition of histone H3.3, were identified in glioblastoma and were present in 100% of tumors that also contained G34R or G34V mutations in H3.3 itself, raising the possibility of mutations with coordinate effects upon chromatin structure.[110] Mutations in *ATRX* also occur in older patients with neuroblastoma.[78] Collectively, chromatin modifiers have emerged as a major new class of tumor suppressors.

SPLICING FACTORS

In addition to mutations affecting factors that regulate chromatin, recent studies have also identified recurrent mutations of genes encoding components of the spliceosome, including mutations of the *U2AF35*, *ZRSR2*, *SRSF2*, and *SF3B1* genes in myelodysplastic syndromes, AML, and juvenile myelomonocytic leukemia.[128,129] The mutations tend to be missense and mutually exclusive, and they cluster in distinct conserved parts of the genes, suggesting gain-of-function phenotypes. All of these genes encode components of the spliceosome that are involved in splicing of pre-mRNAs, suggesting that their tumorigenic mechanism may involve dysfunctional control of gene expression arising from aberrant mRNA splicing. Indeed, mutated splicing factor gene products participate in the 3′ splice site selection during pre-mRNA processing, inducing abnormal splicing in reporter assays.[128] However, SF3B1 can also interact with components of the Polycomb complex involved in regulation of chromatin structure and gene transcription, raising the possibility that its mutation and tumorigenesis may involve mechanisms other than splicing.[130] Because transcription and splicing are often coregulated in normal cells and mutations of splicing factor genes often co-occur with mutations affecting regulators of gene expression in tumor cells, a definition of their tumorigenic mechanisms and phenotypic consequences may require a comprehensive analysis of the potential interactions of the co-occurring mutations.

METABOLIC ENZYMES

Another unanticipated finding from the analysis of tumor genomes has been the discovery of mutations in metabolic enzymes. Initially observed in gliomas, missense mutations of the isocitrate dehydrogenase 1 and 2 *(IDH1* and *IDH2)* genes that encode isocitrate dehydrogenase enzymes, which are components of the mitochondrial citric acid cycle, have also been found in a large fraction of AMLs.[131,132] The majority of mutations involve conserved arginine residues in the enzymatic active sites, which aberrantly generate 2-hydroxyglutarate that accumulates to high concentrations in tumor cells, tissues, and even circulating blood.[133,134] Because 2-oxoglutarate, the normal metabolite of *IDH1* and *IDH2*, is an essential cofactor of many cellular enzymes, the effects of oncogenic *IDH1* and *IDH2* mutations and excess production of 2-hydroxyglutarate may be pleiotropic.[135] Indeed, *IDH1* and *IDH2* mutations can lead to the inhibition of enzymatic activity of *TET2* that hydroxylates 5-methylcytosine in DNA, as well as associated changes in DNA methylation and gene expression in leukemia cells.[136] Mutations of IDH and production of 2-hydroxyglutarate have also been found to inhibit H3K9 demethylase KDM4C in glioma cells.[137] In addition, in glioma cells, generation of 2-hydroxyglutarate by mutant IDH enzymes also inhibits EGLN prolyl hydroxylases, leading to diminished hypoxia-inducible factor levels and enhanced cell growth.[138]

The stereospecific nature of the effects of 2-hydroxyglutarate—wherein the (R)- but not the (S)-enantiomer appears to be oncogenic yet both metabolites can inhibit 2-oxoglutarate–dependent cellular enzymes—may lead to the definition of specific mechanisms and their ultimate therapeutic blockade.[139] Mutations of other metabolic enzymes, such as succinate dehydrogenase and fumarate hydratase, can also be tumorigenic, causing gastrointestinal stromal tumors, paragangliomas, and renal cell carcinomas,[140] which suggests that aberrant metabolic properties of cancer cells may be not only adaptive but in and of themselves tumorigenic.

CONCLUSIONS AND FUTURE OUTLOOK

The study of the genetic basis of pediatric cancers has revealed important principles of human carcinogenesis that help explain the diverse traits of cancer cells. In particular, the study of human cancer predisposition syndromes, many of which clinically present in childhood, has established the prevalence of mutations of tumor suppressor genes and oncogenes that cause the dysregulation of cell growth, DNA repair, and gene expression in human cancers. These studies have also established the essential contributions of the cellular state on the effects of tumorigenic mutations, with the same mutations having distinct functional consequences and phenotypic effects that depend on the cancer cell of origin. Likewise, the increasing recognition of epigenetic alterations in human cancers may reveal fundamental developmental pathways that are required for normal and cancerous cell growth. Finally, because tumorigenesis is inherently a multistep process, the accumulation of genetic lesions that ultimately lead to symptomatic disease is nonrandom, establishing discrete combinations of molecular lesions that functionally cooperate to transform cells. As a result, the clonal structure of tumors is organized hierarchically, and its future study will reveal important principles of biologic cell function and dysfunction. This notion is further bolstered by the frequent observation of somatically acquired gene mutations that are rare when considered individually but involve coherent biologic pathways that are mutated frequently as a functional group. Consequently, future studies of the biologic basis of human cancer that are faithful and therapeutically relevant may necessitate the generation of compendia of molecular lesions and cancer models based on such ontogenies.

CONCLUSIONS

With the discovery of nitrogen mustard as an anticancer agent in the 1940s, medicinal and hence systemic cancer therapy became a reality. The identification and application of cytotoxic agents dominated the next 60 years of cancer treatment. The success of imatinib for *BCR-ABL* rearranged chronic myelogenous leukemia (CML), the dramatic responses seen in patients with *BRAF*-mutated melanoma and *ALK* rearranged non–small cell lung cancer to targeted inhibitors, and the unparalleled ability to systematically characterize cancer genomes have catapulted the community into a new era of targeted cancer therapy. Nonetheless, there is much to learn from the 60-year experience in empiric-based therapy that should be directly applicable to the development of molecularly targeted therapy. Cytotoxic chemotherapy, although often regarded as largely unsuccessful, has led to substantial cure rates in a number of well-defined malignancies, particularly pediatric. In this chapter we will discuss the fundamental concepts, advantages, and disadvantages of cytotoxic cancer therapy and their relevance to targeted drug therapy for malignancy. We will define targeted therapy, its advantages and disadvantages, discuss the credentialing of targets, and provide a system for categorizing classes of targets and classes of therapies. We will then focus on particular lessons learned in the early development and testing of new targeted therapies for adult malignancies, with examples from each of the target classes. Our intent is to highlight illustrative examples rather than to provide an exhaustive list of all targeted therapies in development. We will conclude with a discussion of the challenges facing us in the development of targeted therapies for children and highlight emerging pediatric cancer-based targets.

TRADITIONAL CHEMOTHERAPY

Conventional Chemotherapy: Not Entirely Nonspecific

Although conventional chemotherapy agents are often seen as nonspecific cytotoxic drugs, over the years more information has come to light about their mechanisms of action in killing tumor cells. In general, these agents were designed to interfere with molecular pathways required for nucleotide synthesis, DNA replication, and the mechanics of cell division. Thus these agents have significant but often predictable, or at least stereotypical, morbidity related to target-mediated suppression of hematopoiesis or of the cell-division process required for homeostasis of other organ systems. These agents are discussed in greater detail in Chapter 45.

Lessons Learned from Cytotoxic Chemotherapy

The use of cytotoxic chemotherapy agents is an imperfect science at best, but researchers have learned many lessons over the years about the medicinal treatment of cancer,

Box 44-1 Lessons Learned from Cytotoxic Chemotherapy

1. Combination therapy is required for cure.
2. Appropriate dose intensity is required for improved outcome.
3. Toxicity is acceptable when therapy is curative.
4. Establish curative regimens, and then attempt to reduce toxicity.

lessons to strongly consider in the development of targeted therapy (Box 44-1).

Combination Therapy Is Required for Cure

The goals of combination therapy are numerous. First, because it is difficult to predict which single agent will be most effective against an individual patient's tumor, the use of multiple drugs increases the potential for an initial complete response. Second, combination therapy is likely critical for preventing the development of therapeutic resistance. Third, drug combinations may have additive or synergistic interactions, increasing the total activity of the drugs and potentially enabling lower dosing and reduced toxicity. One example is the successful dose reduction of cytotoxic chemotherapy with the addition of all-*trans*-retinoic acid (ATRA) for the treatment of patients with acute promyelocytic leukemia (APL).[1,2] With few exceptions, curative systemic therapy has required the combination of highly active agents rather than combinations of active and inactive agents.

The need for multiagent therapy was first appreciated in the treatment of acute lymphoblastic leukemia (ALL). At best, 60% of patients are estimated to achieve complete remission with single-agent chemotherapy. Despite continued use, almost all patients will relapse within 6 to 9 months with single-agent therapy. However, complete remission rates exceed 95% in patients treated with combination chemotherapy, and cure rates today for children with ALL exceed 80% with multiagent treatment regimens.[3,4] Similarly, patients with APL had very poor remission and cure rates until the discovery of ATRA differentiation therapy for this disease. ATRA achieved a high complete remission rate in use as a single agent, but virtually all patients ultimately relapsed.[5,6] It was not until the combination of cytotoxic chemotherapy with ATRA and the recent combination of ATRA with arsenic trioxide that these patients obtained the best long-term survival rates of any acute myeloblastic leukemia (AML) subtype.[1,7]

Appropriate Dose Intensity Is Required for Improved Outcome

A guiding principle in the delivery of cytotoxic chemotherapeutic agents is the concept of the maximum tolerated dose (MTD): the simple idea that more is better. Drugs are delivered at the maximum dose possible, a dose greater than which unacceptable toxicity is encountered. Here, without a clear cellular biomarker of cytotoxic activity, it is not possible to relate the maximum molecular effect to maximum achievable efficacy. Thus cytotoxic drugs are first evaluated in phase I studies with the primary study goal of establishing the MTD. Subsequent phase II and III trials are then based on this dosing schedule. MTD assumes that some toxicity is acceptable and, in fact, expected in the pursuit of cure. The most extreme example of this concept has been the use of autologous stem cell transplantation to deliver what otherwise would be lethal doses of chemotherapy. In this case the MTD is surpassed by replacing the dose-limiting factor, the hematopoietic system, with stem cells harvested from the patient before delivery of the conditioning chemotherapy. While clearly a brute force approach, the MTD paradigm also established an important corollary: significant side effects can be tolerated when therapy is administered with curative intent (discussed later).

Many retrospective studies of chemotherapy dose intensity and outcome support this premise, particularly in the pediatric setting. In high-stage neuroblastoma the addition of dose intensification with stem cell transplantation has improved the outcome for patients with metastatic disease.[8-11] In pediatric ALL several studies suggest that dose intensification is important for long-term outcome, including one randomized study comparing standard versus dose-reduced methotrexate with mercaptopurine.[12-15] Moreover, in Ewing sarcoma chemotherapy intensification through interval compression in a randomized trial was also associated with an improved outcome in patients with localized disease.[16] However, fewer prospective studies than retrospective studies have been performed to address the issue of dose intensity and outcome for pediatric tumors. Significantly, while these studies begin to emerge, some previous assumptions about MTD have come into question. For example, retrospective studies support the notion that doxorubicin or methotrexate dose intensity is important for outcome in patients with localized high-grade osteosarcoma.[17,18] However, prospective studies involving large patient numbers have called into question the role of further dose intensification for this disease.[19,20] Furthermore, randomized trials for malignancies such as breast cancer have demonstrated that massively increasing dose with stem cell transplantion does not always improve long-term survival.[21,22] Well-controlled prospective trials are critical to address the issue of dose intensification, even for cytotoxic agents.

Toxicity Is Acceptable When Therapy Is Curative

The oncology community has accepted toxicity as inherent in the mission of cure. With the implementation of dose-intensive regimens, however, comes additional toxicity. Because of the relatively nonspecific nature of traditional chemotherapy, morbidity from these treatment regimens is significant. Acute toxicity takes the form of infection, transfusion dependence, renal injury, and hepatic injury. There are also potential long-term consequences such as cardiac injury, infertility, chronic renal insufficiency, hearing loss, skeletal injury, and secondary malignancies.[23] Ongoing efforts are focused on decreasing these short- and long-term side effects. For example, to minimize acute toxicity, chemotherapy dosing is usually individualized on the basis of body surface area (mg/m^2). For some cytotoxic agents, such as methotrexate and busulfan, drug levels can be monitored to minimize toxicity. Dose intensity can also be achieved with regional tumor delivery, growth factor support, or rescue with stem cells. Furthermore, better supportive care, such as infection prophylaxis, has enabled tolerance of prolonged immunosuppression. To decrease long-term morbidity, "safe" maximum cumulative doses are being established, such as maximum cumulative doxorubicin to minimize late cardiac effects. Although toxicity can be tolerated, it is essential that the level of toxicity be commensurate with the level of benefit. Marginally effective therapeutic regimens that result in substantial toxicity should not become accepted standards.

Establish Curative Regimens and Attempt To Reduce Toxicity

Treatment strategies for most of the pediatric malignancies, including ALL and the solid tumors, have used disease stratification to decrease dose in treatment regimens. A dose-intensive regimen is initially used to establish efficacy. Then, patients with a good prognosis are treated with less intensive regimens, with the goal of comparable disease-free outcomes but decreased treatment-related morbidity. This is particularly important for pediatric disease, in which the long-term toxicity of treatment is experienced over a lifetime. Historically, these stratifications were based on factors such as age, stage, and histology, but now they include molecular genetic markers, such as *MYCN* amplification in neuroblastoma, and *MLL* rearrangement in pediatric ALL. For example, the National Wilms'Tumor Study evaluated a half-dose chemotherapy regimen for infants with low-risk disease in an attempt to decrease the incidence of toxic deaths without compromising long-term survival. These infants had acceptable toxicity with no toxic deaths, and long-term survival was not compromised.[24] A similar approach has been taken with infants and young children with low-stage neuroblastoma,[25,26] and therapy for children with ALL has been dose-reduced based on rapid clearance of minimal residual disease.[27]

While our understanding of the molecular basis of malignancy improves, so will our ability to develop fine-grained prognostic categories and patient-tailored treatment regimens, perhaps even for traditional chemotherapy agents. While we implement targeted therapy, it is expected that disease stratification and patient selection will be based on molecular genetic findings related to the credentialed target. In the clinical development of targeted therapies, we must continue to consider these key concepts: combination therapy, appropriate dose intensification, tolerance of toxicity for substantial efficacy and cure, and treatment adjustment within established favorable prognostic groups.

Shortcomings of Cytotoxic Chemotherapy

Although clinicians have made great progress with the cytotoxic armamentarium, further strides in the treatment of cancer are limited with this approach alone. Several shortcomings of this approach are intimately related to the lack of specific target knowledge (Box 44-2).

1. Toxicity is significant.
2. Optimization of anticancer effect versus side effects is difficult.
3. Mechanistic understanding of nonresponding and resistant disease is lacking.
4. Predictors of patient response to a specific drug are poor.
5. To date cytotoxics have explored a narrow range of cellular and molecular mechanisms.

Box 44-2 Shortcomings of Cytotoxic Chemotherapy

1. Toxicity is significant.
2. Optimization of anticancer effect versus side effects is difficult.
3. Mechanistic understanding of nonresponding and resistant disease is lacking.
4. Predictors of patient response to a specific drug are poor.
5. Cytotoxics have explored a narrow range of cellular and molecular mechanisms.

One major shortcoming to cytotoxic therapy is morbidity. Because these agents are relatively nonspecific, there is significant toxicity to normal host cells. Patients can expect to experience short- and long-term morbidity from these drugs and even incur the risk of therapy-related fatality. Furthermore, because the most relevant targets of these drugs are poorly understood, it is difficult to optimize the anticancer effect versus the toxicity, and it is difficult to separate on-target from off-target toxicities. Often, there is no relationship between the administered dose (pharmacokinetics) or the MTD and inhibition of the putative target (pharmacodynamics). Developing a strong correlation between the pharmacokinetics of a drug and its pharmacodynamic effect is obviously impossible when the target of a drug is unknown. Similarly, in the absence of target knowledge, our understanding of resistant or refractory disease is poor at best, and it is very difficult to predict responders a priori. This has necessitated long clinical development programs with large trials to identify responsive subpopulations of patients and then follow-up trials to more thoroughly investigate response in this patient subset. Targeted therapy has the potential to address these shortcomings, to enable more rational tumor-specific therapy with less morbidity risk, and to explore previously unexploited cancer-related molecular mechanisms. With the sequencing of the human genome, the development of high-throughput genomic technologies, and an ever-increasing understanding of the molecular pathogenesis of cancer, this promise is likely to be realized.

INTRODUCTION TO TARGETED THERAPY

What Is Targeted Therapy?

Although we have made great strides with the cytotoxic armamentarium, further strides in the treatment of cancer are limited with this approach alone. We still fail to cure many patients with this approach, and several shortcomings of this approach are closely related to the lack of specific target knowledge (see Box 44-2). Targeted therapy, defined as a therapeutic procedure whose preclinical development focused on modulation of a single molecular target (typically inhibition but occasionally activation of the molecular entity), has the potential to address these shortcomings. Targeted therapy relies on the concept of cancer cell dependence—that is, the malignant cell or tumor as a whole depends for its survival or proliferation on the particular gene product or pathway. The discovery of targeted therapy differs significantly from that of cytotoxics. Historically, cytotoxic therapy discovery relied on simple, phenotypic cell death assays in which small-molecule libraries were screened in vitro against a panel of cancer cell lines. Because cytotoxic compounds are believed to cause nonspecific cell death, effective compounds should, in principle, have efficacy for all cancer types. In practice, however, this has not proved to be the case. Thus although phenotypic screens may be of significant value in identifying molecules with complex mechanisms of action, the direct prediction of clinical efficacy from limited in vitro testing remains problematic. This is in sharp contrast to the concept of targeted therapy.

There are three critical elements to the implementation of targeted therapy. First, on the basis of available data, a hypothesis is generated suggesting a causal or pathogenic link between a specific protein or gene (the potential drug target) and cancer. Experiments are then performed and data generated to test the validity of this hypothesis. Is this candidate target relevant to oncogenesis or the maintenance of the malignant phenotype? Second, there must be a valid therapeutic approach to interfering with the target activity through small molecules, antibodies, or protein- or cell-based biologics. Third, the clinician must estimate the likely impact of target manipulation in a relevant clinical application. For example, a targeted therapeutic may have limited clinical application if the disease state is already readily cured. The process of evaluating potential targets that emerge is target "validation."

Advantages of Targeted Therapy

Targeted therapy offers several potential advantages over nonspecific cytotoxic treatments (Box 44-3).

1. Improved patient selection is enabled.
2. Drug efficacy and target inhibition are linked, enabling rational dosing.
3. Side effects are more predictable.
4. Understanding of target and pathway increases options for the subsequent development of therapeutics with improved efficacy.
5. The mechanisms of resistance may, in some cases, be more readily discovered and interdicted with second-generation therapeutics or specific combinations.
6. Rational pathway-based combination regimens can be tested.

By way of example, hormonal therapy has become standard of care for patients with estrogen receptor (ER)–positive breast cancer. In this case there is a lineage-dependent target in the malignant cell, the ER, and antiestrogen agents, such as tamoxifen, have been developed to inhibit competitive binding of estrogen to the ER. Numerous studies exploring estrogen antagonist therapy with tamoxifen for patients with ER-positive versus ER-negative disease demonstrate benefit only in the ER-positive patients.[28-31] In conjunction with diagnostic tools to identify hormonal receptor status, patients are now rationally chosen for therapy, thus eliminating exposure to drug toxicity for patients not likely to respond.

A second advantage of targeted therapy is the strong link between the target inhibition and efficacy. The dosing goal is achievement of complete target inhibition, not MTD. Thus there is no need to suffer undue toxicity in the achievement of an MTD. In fact, studies have shown that tamoxifen treatment responses do not correlate with serum levels and that doses greater than 20 mg daily do not increase efficacy compared with that of this dose.[32] A related third advantage of targeted therapy is that the side effects can generally be anticipated and serve as a marker for on-target inhibition. For example, the side effects of tamoxifen are predominantly related to the antiestrogen effects of this drug: vaginal dryness, hot flashes, and irregular menses. Because this drug also has proestrogen effects, thromboses and endometrial cancer can be seen.

A fourth advantage of targeted therapy is that understanding the target and the pathway increases the possibilities for therapeutic design. In the case of modifying ER signaling, there are several methods to accomplish this other than direct ER antagonism. One method is to decrease ovarian production of estrogen with luteinizing hormone–releasing factor agonists, which induce a medical ovarian ablation. A second method of interfering with ER signaling is to decrease estrogen production through the inhibition of aromatase activity. Aromatase is the final enzyme in estrogen synthesis converting the androgens androstenedione and testosterone to the estrogens estrone and estradiol. Aromatase inhibitors work by decreasing this conversion and thus decreasing circulating estrogens. Aromatase inhibitors have improved efficacy over tamoxifen and have the advantage of fewer side effects in terms of hot flashes, endometrial disease, and ischemic cerebrovascular effects.[33,34] Because of the clear dependence of some breast cancers on ER and detailed knowledge regarding estrogen biosynthesis and signaling, multiple agents could be developed to inhibit this pathway.

The fifth advantage of targeted therapeutics is the ability to more readily understand the molecular mechanisms associated with resistance. The success of targeted inhibition of BCR-ABL in CML and of epidermal growth factor receptor (EGFR) in lung cancer was rapidly followed by the specific elucidation of direct resistance

Box 44-3 Advantages of Targeted Therapy

1. Improved patient selection is enabled.
2. Drug efficacy and target inhibition are linked, enabling rational dosing.
3. Side effects are more predictable.
4. Understanding of target and pathway increase options for the subsequent development of therapeutics with improved efficacy.
5. The mechanisms of resistance may, in some cases, be more readily discovered and interdicted with second-generation therapeutics or specific combinations.
6. Rational pathway-based combination regimens can be tested.

mutations in the target leading to decreased activity of the relevant small-molecule inhibitors, imatinib and erlotinib or gefitinib, respectively.[35,36] In the case of CML, new agents were developed in short order to treat resistance in patients by more efficient inhibition of the mutant BCR-ABL proteins.[37]

The final advantage of targeted therapies may be the ability to generate rational and novel combination regimens. Currently, the vast majority of combination strategies derive from combining a novel agent with components of existing standards of care without regard to mechanism. This strategy is largely based on clinical expedience, existing clinical efficacy (for the standard of care) and tolerability. The difficulty of empirically discovering new synergistic combinations stems from the large number of permutations required to test all possible combinations against multiple in vitro and in vivo models or multiple cancer types. Targeted therapeutics are often related to one another in the context of a pathway. This allows testing of specific pathway-related hypotheses. For example, combinations might target upstream and downstream components of the same pathway to defeat feedback mechanisms, target components of parallel pathways to defeat pathway redundancy, or target distinct antiproliferative and prosurvival pathways.

Classes of Targets

Much of current cancer therapy development focuses on specific changes that alter the malignant cell, setting it apart from its normal counterpart and creating distinct molecular or pathway dependence for cell survival and replication. These may be genetic mutations, gene rearrangements, epigenetic modifications such as altered patterns of methylation or acetylation, lineage legacies, or other metabolic liabilities. Genes whose expression and activation have been increased, resulting in a cancer-dependent state, are prime targets for therapy development. On the basis of cancer dependencies, cancer targets can be categorized in four classes: genetic, lineage, host, and synthetic lethal or empiric (Box 44-4).[38] Although some targets may cross over from one class to another, this classification may be useful in the design of clinical trials and elucidation of the parallel biomarker strategy.

Genetics Track

The genetics track relies on the idea that a cancer develops from a finite number of genetic alterations, that these alterations give the malignant cell a selective advantage, and that these genetic changes are selected for during malignant cell replication. Hence the malignant cell becomes dependent on a set of these changes for continued survival, a process sometimes referred to as *oncogene addiction*.[39,40] This cancer cell dependence or addiction should provide a window for drug specificity for the malignant cell compared with normal cells. Targeted therapeutics taking advantage of genetic abnormalities should, in theory, be more injurious to the malignant cell than to the normal cellular counterpart. Advances in cytogenetic studies, high-throughput gene sequencing, detection of copy number alteration, whole genome expression profiling, and proteomic approaches have revolutionized candidate genetic target discovery. Now, tens of thousands of genes in hundreds of tumor samples can be analyzed simultaneously. These candidate targets must then be carefully credentialed for their suitability as a drug target. Is there cancer cell dependence on the genetic abnormality, and can the target be pharmacologically manipulated? Imatinib is one of a number of examples of clinically validated targeted therapeutics exploiting a genetic dependence, in this case the dependence of CML on the activity of the Abelson kinase (ABL). The very existence of the cancer-dependent state is dramatically illustrated by the emergence of resistance mechanisms that largely appear to restore Abelson activity (see further discussion later in this chapter).

Box 44-4 Classes of Targets

1. Genetics track
2. Lineage track
3. Host track
4. Synthetic lethal or empiric track

Lineage Track

Cancer cells often maintain developmental features of the lineage from which they were derived. This is well supported with gene expression studies that report tumor cells more closely resembling the normal lineage counterpart than tumors of a different cell type. The notion that lineage or "legacy" features of a tumor cell may be exploited with targeted therapy is known as *lineage addiction*.[41] One of the earliest examples of the success of this approach has been the antagonism of ER and its signaling pathway in patients with ER-positive breast cancer. Similarly, the vast majority of patients with prostate cancer derive significant benefit from antagonism of the androgen receptor (AR). In both ER-positive breast cancer and in prostate cancer (virtually all forms of which express AR), the emergence of hormone-refractory disease largely appears to rely on mechanisms that restore steroid receptor signaling.[42] Thus as in the case of imatinib resistance, the dependent state is illustrated by these resistance mechanisms. In many cases lineage dependence may also derive from the normal hierarchy of differentiation beginning with the stem cell.

Host Track

The importance of tumor cell environment to the development and maintenance of the malignant state has become increasingly recognized and represents another potential inroad to targeted therapy. It is possible that tumors, by evolving in a particular environmental context, may become dependent on certain growth factors or neighboring cells for survival in that niche. Preclinical evidence suggests that many tumors require de novo blood vessel development for their growth and maintenance. The identification of these angiogenesis factors has enabled the development of modifiers of the angiogenesis process, leading to the successful clinical application of bevacizumab, an anti–vascular endothelial growth factor

(VEGF) antibody, in patients with colorectal cancer and the approval of kinase insert dependent receptor inhibitors (sunitinib and sorafenib) in renal cell carcinoma (see further discussion later in this chapter). The interaction of tumors with the bone microenvironment has also been targeted using inhibitors of osteoclastogenesis. Here, multiple bisphosphonate agents are approved for the prevention of cancer-related fractures.[43]

Synthetic Lethal or Empiric Track

A number of highly efficacious anticancer agents do not conveniently map to the first three categories. Admittedly, we can say that the understanding of the mechanisms of efficacy of such agents remains opaque. Nonetheless, it is quite likely that such agents, including many of the cytotoxic agents described previously, take advantage of aspects of cancer cell biology that remain unknown but may be broadly termed as *synthetic lethal interactions*. Synthetic lethal genetic interactions are defined as mutations that are lethal in combination but that do not produce a lethal phenotype as a single event. In a similar way, gain-of-fitness alterations in a malignant cell, which give the cell a survival advantage, can sensitize the cell to other stresses that have no consequence in a normal state but may be lethal with the malignancy promoting alteration. Thus cancer-promoting mutations give the malignant cell a survival advantage, but they may also incur a distinct liability that can be exploited therapeutically. Rather than two synthetic lethal genetic events, the clinician can also apply such synthetic lethal concepts to a preceding cancer-related molecular alteration followed by the application of a therapeutic. For example, a striking synthetic lethal relationship was discovered between loss of BRCA1 or BRCA2 function and inhibition of the poly(ADP-ribose) polymerase I enzyme (PARP). Here, loss of PARP1 was found to induce double-strand DNA breaks that required the recruitment of the RAD51 homologous recombination repair complex to the site of these breaks for effective repair. Because it was known that BRCA1 and 2 were required for RAD51 recruitment to such complexes, it was hypothesized that loss of BRCA1 or BRCA2 would create sensitivity to PARP inhibition. This was demonstrated both with siRNA and small-molecule inhibitors of PARP.[44] Moreover, clinical activity of PARP inhibitors has now been seen in patients with *BRCA1* and *BRCA2* mutations with ovarian or breast cancer.[45-48]

Credentialing Targets

By the strictest of measures, a drug target is not validated until a selective inhibitor of the target of interest has proven clinical activity *and* when resistance emerges through specific alterations in the direct target. Although very few cancer targets have achieved this degree of validation, we can envision preclinical experimental methods that will allow the researcher to credential a target for further drug discovery efforts. In this effort, the goals are to build data sets that either prove or disprove certain target-based hypotheses and to use such data sets to prioritize target selection for future drug discovery efforts.

Functional validation: study of a target in a model system of tumor biology
  Gain-of-function: address sufficiency of target
  Loss-of-function: address necessity of target

We can consider three key questions regarding the relevance of any given target to anticancer therapy:

1. Is the activity of the target required for the development and maintenance of the cancer-dependent state?
2. Is it possible to identify a strategy for developing a therapeutic for the target of interest?
3. Is there a clinical application for the eventual therapeutic?

In the subsequent sections we will focus on the approaches relevant to addressing the role of a given target in cancer dependence. In this specific regard there are two general sources of information: the study of a target in human cancers (target epidemiology) and the functional study of a target in model systems of tumor biology (functional validation) (Box 44-5).

Target Epidemiology

Preclinical models of cancer are limited in both number and in their qualitative relationship to human cancers. Comprehensive collection of human tumor specimens could, in theory, be used to study a given target in a large array of samples broadly covering tissue distribution and stage distribution (primary versus metastatic sites). In practice, however, there are limited sets of comprehensive tumor collections, and generally the largest tumor-type specific collections are limited to fixed, paraffin-embedded specimens. The availability of tissue samples paired with robust clinical data remains limited. Furthermore, the vast majority of human cancer collections come from surgical resection samples, which do not necessarily reflect the disease state in which a therapeutic will be initially tested. Despite these limitations, molecular epidemiology studies in tissue samples, enabled by tissue microarrays, single nucleotide polymorphism (SNP) arrays, expression microarrays, reverse protein arrays, and next-generation sequencing technologies remain critical to building a case for the cancer relevance of a given target.

Target Expression. The desire to discover genes "selectively" expressed in cancer led first to the development of differential expression methods, including the subtractive hybridization cDNA libraries, differential display, and serial analysis of gene expression (SAGE) as examples.[49,50] Following the elucidation of the human genome sequence and the development of DNA-based microarrays, comparative expression profiling largely replaced difference methods, and more recently, RNA sequencing has become a commonly used tool. In all cases the basic premise has been to identify genes overexpressed in cancer with the assumption that overexpression will equate with increased sensitivity to target inhibition and hence serve to improve the therapeutic index. This basic idea, however, must be challenged and carefully considered for each target, for the simple reason that resistance to therapeutics can likewise be engendered through overexpression. Indeed, on the basis of standard biochemical principles, increased target expression should necessitate a higher drug concentration to achieve target inhibition. This is clearly the case in the amplification of dihydrofolate reductase (DHFR) in generating resistance to methotrexate.[51] Likewise, data suggest that increased expression of AR can lead to resistance to AR blockade.[42] Thus caution is required before proceeding with target selection based solely on expression data in the absence of a demonstrated causal or functional link to the maintenance of a cancer state.

Genetic Alterations. As illustrated by the success of ATRA, trastuzumab, and imatinib, direct genetic alteration leading to gene activation of a given drug target remains perhaps the best evidence for the causal role of a given gene in carcinogenesis. Genetic alterations that are highly frequent in a given tumor type and are present in the majority of cells are a strong indicator of causality. In the era of large-scale resequencing projects, it is critical that one distinguishes "driver" mutations (causal mutations) from so-called passenger mutations.[52] In addition, driver mutations that arise late in the course of disease, are present in only a minor fraction of the tumors, or are present in only a fraction of tumor cells in a given single tumor must be given less weight. These findings would suggest a reduced likelihood of this lesion possessing a strong causal link to the initiation of the disease state, although they may pose an eventual mechanism of drug resistance. The types of genetic alterations (e.g., point mutations, focal amplifications, broad amplifications, and translocations) are also distinguished with respect to the extent to which they can be used to establish causality or to infer dependence.

Gain-of-Function Genetic Alterations. Gain-of-function genetic alterations include translocations, activating point mutations, and increases in gene copy number. Translocations were among the first discovered genetic alterations initially described using chromosome spreads. Approaches to the discovery of chromosomal rearrangements include exon microarrays, which can potentially detect imbalanced or amplified translocations, cancer outlier profile analysis (COPA), paired-end resequencing of BAC clones from a genomic library (giving a structural map of a cancer genome),[53] and newer methods of single-molecule sequencing (discussed later). Translocations are highly informative with respect to causality because they typically alter only two genes, and because background or random translocation events are relatively rare, with chromothripsis (massive DNA rearrangements affecting one or a few chromosomes that occur as a result of one catastrophic event) as a notable exception.[54]

Amplifications are now routinely detected by methods of DNA copy number analyses: comparative genomic hybridization (CGH) array, high-density SNP arrays, and whole exome or whole genome sequencing. There are two general types of increases in gene copy: focal amplifications and broad copy number increases covering an entire chromosome or chromosome arm. With sufficient sample numbers it is possible to discern one to several genes contained within a focal amplicon. Typically, the minimal region of amplification is a guide. However, methods for detecting copy number alterations (e.g., genomic identification of significant targets in cancer [GISTIC]) also use the amplitude of amplification as an important parameter.[55] Although it is not definitive proof, amplification lends evidence to a causal relationship between a given gene within an amplicon and a cancer state. In some amplicons, multiple genes remain strong candidates for oncogenes targeted by the amplification. One notable example is the 11q13 amplification with genes including *Cyclin D1*, *FGF3*, and *FGF4*.[56]

Larger-scale chromosomal alterations leading to trisomy or gain of an entire chromosome arm are frequent yet are far more difficult to study. As such, identifying single genes (or drug targets) within such broad regions remains a challenge. In this case the number of genes implicated in such large-scale alterations is so large that almost no importance can be ascribed to the cancer relevance of a gene contained within such broad chromosomal-level alterations. Outlier analysis may begin to allow the elucidation of multigene targeting by such broad regions and is illustrated by the analysis of trisomy 7 in glioma revealing a dependence on cMET and its ligand HGF, both located on chromosome 7.[57]

Subtle nucleic acid level alterations, including point mutations and small insertions and deletions, are an important mechanism for the activation of oncogenes. Point mutations leading to the constitutive guanosine triphosphate (GTP)–bound and hence activated form of N-RAS and K-RAS,[58] as well as genetic events leading to activation of the BRAF kinase in melanoma, thyroid cancer, colorectal cancer,[59] pediatric pilocytic astrocytoma,[60-62] and Langerhans cell histiocytosis[63] are exemplars of this mechanism. Large-scale sequencing projects that unveiled new mutations activating oncogenes such as *EGFR*[36] and *PIK3CA*[64] have led to national and international cancer genome sequencing projects. From these studies it has become apparent that the detection of passenger mutations, constituting the background rate of mutation, can pose a significant challenge. These passenger mutations must be separated from the more prevalent and recurrent driver mutations.[52] Such passenger mutations may be exceedingly high in certain types of tumors, particularly those bearing mutations in mismatch repair genes. Indeed, in one case inactivating mutations in the mismatch repair gene *MSH6* were discovered in glioma tumors recurring after treatment with temozolomide. Here the sequencing of *MSH6* was triggered by the very high rate of observed passenger mutations in treated versus untreated tumors.[65,66] These data suggest that cautious interpretation of low-frequency events is warranted when considering mutation analysis from larger-scale modalities. A framework for context-specific mutation analysis has been provided by a systematic study of mutation data across many cancer types in The Cancer Genome Atlas (TCGA) project and others, and these studies are revealing remarkably simple genomes in many pediatric cancers (Fig. 44-1).[67]

Loss-of-Function Genetic Alterations. Loss-of-function alterations do not typically directly indicate or point to a specific gene as a candidate drug target. However, such alterations may predict sensitivity to agents acting against protein targets contained within downstream or parallel pathways. For example, clinical trials are under way testing inhibitors of mammalian target of rapamycin (mTOR) function against sporadic tumors or hereditable cancer predisposition syndromes resulting from loss of the tumor suppressors PTEN and TSC1 or TSC2. In both cases loss-of-function mutations in these tumor-suppressor genes are thought to lead to constitutive activation and hence constitutive dependence on mTOR (discussed later in this chapter).

Similarly, in the hedgehog pathway, a key development pathway regulating cell patterning, deletions or mutations in the gene encoding the Patched receptor (PTCH) are associated with hereditary and sporadic basal cell carcinomas and sporadic medulloblastoma.[68-70] Loss of PTCH, a receptor for the ligands in the hedgehog family, leads to constitutive activation of the atypical G protein–coupled receptor (GPCR)–like protein Smoothened (Smo).[71] Cyclopamine, a naturally derived inhibitor of Smo, and other, newer small-molecule inhibitors, have had significant activity in preclinical models lacking *PTCH* gene function[72] and in clinical trials.[73,74] These examples illustrate that identification of loss-of-function mutations can reveal downstream target molecules in critical cancer pathways.

Translocations are typically thought of as gain-of-function genetic events in that they act dominantly. However, they can functionally inactivate endogenous genes through the creation of dominant-negative protein fusions. For example, the PML-RARα fusion protein is believed to act, at least in part, as a dominant-negative inhibitor of endogenous RARα function.[75] This type of molecular action can be difficult to elucidate in functional experiments. Nonetheless, it is worth remembering this possibility when evaluating proteins or genes as drug targets when they are involved in new or existing translocations.

Chromosomal-level alterations leading to loss-of-function events include homozygous deletions, heterozygous deletions, and loss of heterozygosity. Homozygous deletions are typically highly focal in their nature. When the boundaries are defined with large sample sets, in

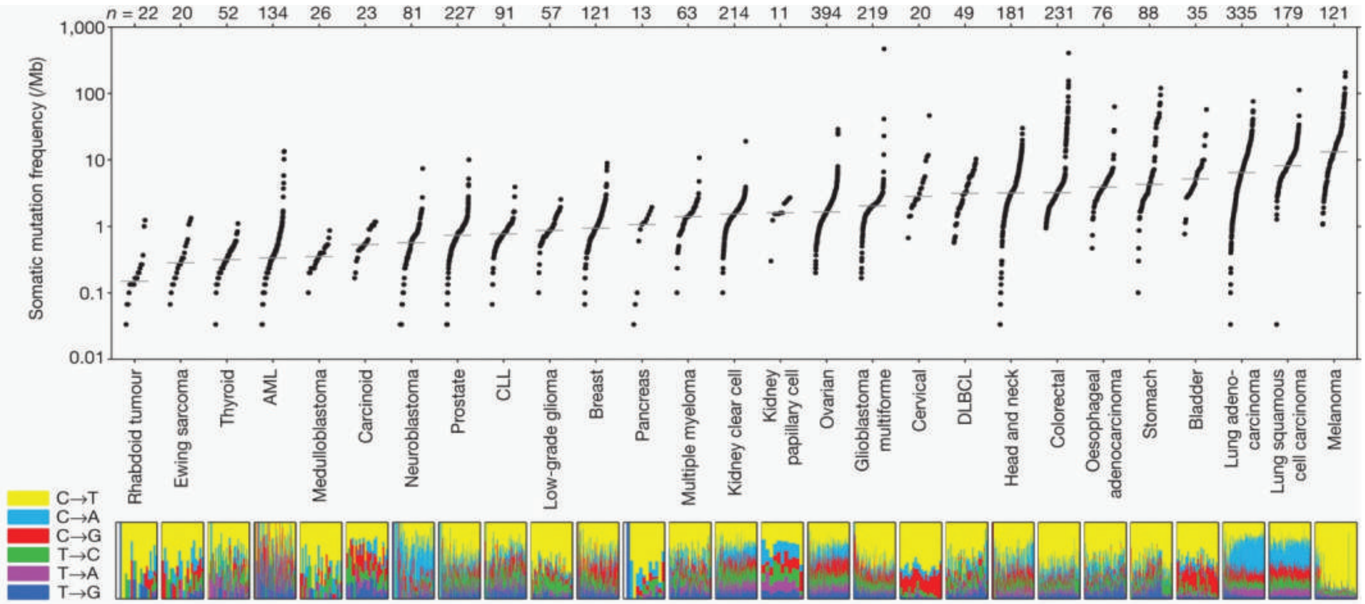

Figure 44-1 Somatic mutation frequencies observed in exomes from 3083 tumor-normal pairs. Each *dot* corresponds to a tumor-normal pair, with vertical position indicating the total frequency of somatic mutations in the exome. Tumor types are ordered by their median somatic mutation frequency, with the lowest frequencies *(left)* found in pediatric tumors and hematologic malignancies, and the highest *(right)* in tumors induced by carcinogens such as tobacco smoke and ultraviolet light. Mutation frequencies vary more than 1000-fold between lowest and highest across different cancers and also within several tumor types. The *bottom panel* shows the relative proportions of the six different possible base-pair substitutions, as indicated in the label on the left. *AML,* Acute myeloblastic leukemia; *CLL,* chronic lymphocytic leukemia; *DLBCL,* diffuse large B-cell lymphoma. *(Modified from Lawrence, et al: Mutational heterogeneity in cancer and the search for new cancer-associated genes.* Nature *499:214–218, 2013.)*

many cases, only a few genes are found in the overlapping region. For example, in the case of focal deletions on 9p, the typical minimal deleted regions in tumors such as melanoma contain only *CDKN2A* and *CDKN2B*.[76] Heterozygous deletions are typically larger and usually involve entire chromosomes or chromosome arms. As in the case of amplifications, such large-scale broad genetic alterations make it difficult to ascertain the cancer relevance of any single gene contained within a larger region. Loss of heterozygosity (LOH) can occur as an event associated with heterozygous deletion leaving only one parental chromosome behind, which is thus homozygous. LOH can also occur when duplication of the remaining parental chromosome creates a situation known as *uniparental disomy.* This is significant because it may indicate preservation of a mutated allele, leading to two mutant alleles of a given gene. In the case of the tumor suppressor gene *p53*, copy-neutral LOH is common.

Inactivating point mutations are a common means of gene inactivation. In this case stop codons are the most efficient mechanism for disrupting gene function. As a result, tumor suppressor gene mutations often are enriched for stop or truncating mutations. This creates certain technical and cost difficulties in sequencing genes for inactivating mutations because it is necessary to sequence all coding exons, consider sequencing of the regulatory elements governing splicing, and consider the detection of promoter mutations. As a result of these difficulties, precise clinical analysis of tumor suppressor gene mutations remains challenging even with the application of next-generation sequencing technologies.

Protein Molecular Epidemiology by Immunohistochemistry. It is important to understand the relationship between the expression or activity of a gene product and patient outcome or other clinicopathologic data. Although establishing a relationship between protein expression and clinical data (e.g., survival) does not provide a causal link to cancer, such linkage to patient outcome likely indicates a nonrandom association with cancer behavior. Here the clinician should be careful to consider the relationship between protein expression and the state of differentiation of the cancer. Because the degree of cancer differentiation state (usually referred to as *grade*) is typically already linked to patient prognosis, candidate drug targets whose protein levels vary with differentiation state may be secondarily linked to patient outcome. Thus an independent association between a protein's expression and patient outcome should be sought in multivariate analysis. In the case of the targeted disruption of HER2 in patients with breast cancer, the association of *HER2* amplification with poor outcome provided a significant motivation for the development of trastuzumab, an anti-HER2 monoclonal antibody.[77]

The ability to perform larger-scale epidemiology analyses typically relies on archived tissue for which longer-term clinical follow-up is available. This largely dictates that target epidemiology be carried out in paraffin-embedded, fixed tissue. Here RNA and DNA can be examined by in situ hybridization (ISH), fluorescence in situ hybridization (FISH), or next-generation sequencing approaches. Historically, the most common method for interrogating human tissue samples is protein-based immunohistochemistry (IHC). These studies have been made higher throughput by the advent of tissue microarrays. Such arrays align hundreds of tumor samples on a single slide, facilitating the experimental procedures. IHC is primarily limited by the quality of the antibody reagents that are used and the care with which such reagents are subject to rigorous validation. Too often, poorly described or unvalidated antibodies are used in IHC studies after a quality assessment based solely on the observed staining pattern in tissue sections. In all cases where IHC is used, the controls should include experimental, fixed cell blocks derived from negative control cells or tissues known to lack the antigen of interest and positive control cells or tissue known to harbor the antigen of interest. These controls can typically be obtained from blocks created from cell lines where the negative controls can be generated by using short hairpin RNA (shRNA). With the development of protocols for next-generation sequencing from paraffin-embedded tissues, the use of such approaches has become more commonplace for the interrogation of archived primary patient tissues.[78,79]

Functional Studies to Address Cancer Dependence

Ideally, the functional relevance of a putative cancer target should be elucidated before embarking on the lengthy process of drug discovery. The concept is simple: It is preferable to "fail" or invalidate a putative target in preclinical studies than to fail later in the clinic. Although there are multiple reasons for the failure of a given therapeutic in clinical development, ideally failure should be avoided because the drug is made against an irrelevant target. Hence one should develop a robust understanding of the science surrounding a given drug target and tie this scientific understanding to cancer-relevant processes. It is useful to consider two questions in the context of designing experiments for functional validation. First, is the putative cancer target *necessary* for the maintenance of a cancer-related phenotype? Second, is the putative cancer target *sufficient* for inducing a cancer or transformation-related phenotype? These questions are generally answered by experiments directed at inducing loss of function of the target (addressing necessity) and by experiments directed at inducing gain of function (addressing sufficiency).

Gain-of-Function Experiments. Gain of function of a given protein typically involves overexpression of the cDNA or of an activated allele generated by mutation. The functional consequences of gene activation are assayed first in in vitro growth assays, in transformation assays, and in cotransformation experiments. Typically, gain of function in transformation assays would be assessed in murine embryonic fibroblasts, in immortalized NIH3T3 cells, Ba/F3 cells, or in Rat1a fibroblasts. In addition, the ability to transform human primary epithelial cells has been made possible through the use of telomerase and has provided a set of assays that can be used to measure the ability of a given gene to induce transformation in human cells.[80]

Short-term validation experiments using in vivo systems have become more attractive with the advent of tissue reconstitution murine models, enabling rapid genetic manipulation. Examples of this approach include the use of murine hematopoietic cells or murine fetal hepatoblast cells. In each case retroviruses directing the expression of the relevant candidate oncogene can be introduced into the respective primary cells that are then re-introduced into host animals. As an example, mutations in *JAK2* discovered in myeloproliferative syndromes recapitulate the disease entity when re-introduced in retroviral vectors into the hematopoietic reconstitution system.[81-83] Similarly, the use of hepatoblasts has been useful in demonstrating that certain gene activation events can induce hepatocellular carcinoma.[84,85] These systems provide some of the speed and flexibility of in vitro systems but maintain the more authentic relationship between stroma and the generated tumor cells.

Fully genetically engineered models, including transgenic mice, can be useful in studying gene activation in the specific tissue of origin depending on the extent to which promoter regulation can be used to direct gene expression to the indicated cell. Knock-in animals have also been generated in which mutant *RAS* alleles are re-introduced into the endogenous murine *RAS* gene locus.[86] Such animals have been used to demonstrate sufficiency of *K-RAS* for the induction of lung adenocarcinomas,[86] carcinomas of the pancreas[87] and myeloproliferative disease.[88] These engineered models also provide a stable resource for testing candidate drug compounds in highly defined mechanistically driven models.

Loss-of-Function Experiments. For many years there were no feasible methods for readily inducing loss-of-function alterations in mammalian systems. Consequently, the elaboration of a cell-penetrant small-molecule inhibitor or tool compound was one of the only ways to achieve the desired inhibitory effect. The development of robust small interfering RNA (siRNA) methods, taking advantage of the endogenous siRNA processing systems, now allows for transient, stable, or regulated knockdown of nearly any mammalian gene product.[89,90] Genome-editing technologies, such as transcription activator-like effector nucleases (TALEN) and the CRISPR (clustered regularly interspaced short palindromic repeats)/Cas system have also been developed to enable targeted gene-disruption events.[91,92] These powerful new tools are complemented by existing methods for loss-of-function experiments, including the use of inhibitory antibodies for extracellular targets, soluble protein traps for extracellular ligands and receptors, dominant-negative proteins expressed from cDNAs, murine germline knockouts, and inducible knockouts. Generally, loss-of-function experiments would be attempted first in human cancer cell line models. Increasingly, cell line models are being characterized in greater genetic detail, enabling more rational selection of models for functional inactivation experiments by either small molecules or genetic perturbations.[93,94,95] Additionally, shRNAs have been merged with the bone marrow transplantation and the hepatoblast tissue reconstruction models described previously (Fig. 44-2).[96] Finally, regulated germline shRNAs can now be engineered in the mouse as a rapid method for generating tissue-specific and temporally regulated gene knockdowns.[97]

Genetic Studies in Lower Organisms

The topic of genetic studies in lower organisms is too broad for a complete discussion in this chapter. However, it is worth noting the utility of defining genetic dependence in the context of highly conserved pathways that are shared between mammals, flies *(Drosophila melanogaster)* and worms *(Caenorhabditis elegans)*. In some cases lower organisms have a reduced set of homologues for any given pathway member, and thus the necessity of a single gene can be tested directly. Although establishing the relationship between a gene and a cancer phenotype in these organisms is not usually possible, the genetic dependence or epistatic relationships elucidated in such model systems have proved highly informative in humans. A notable example is the discovery of the relationship between loss-of-function mutations in the tuberous sclerosis genes and activation of the mTOR and S6K (ribosomal S6 kinase) pathway (discussed later).

Target Credentialing Summary

The credentialing of drug targets ultimately must be conceived as a set of hypotheses to be tested experimentally. In each case these hypotheses must be built around the relevant biology. It is important to distinguish targets with cell-autonomous effects versus those in which the interaction between cancer cell and host factors is critical. In the case of drug targets that are encoded by bona fide human oncogenes with definitive genetic alterations, one can have a high degree of confidence in the likely therapeutic effect of inhibitory molecules. Unfortunately, this group is the minority of the drug targets for consideration. Thus the intent of credentialing is to enable a rational stratification of potential drug targets and a rational application of resources to specific drug discovery efforts.

Classes of Targeted Therapies

Targeted therapies can be divided into two main classes: drugs (small molecules, natural products, antisense, and siRNA) and biologics (antibody, protein/peptide, and cell-based) (Box 44-6). Biologics, as defined by the U.S. Food and Drug Administration (FDA), include a wide range of products such as vaccines, blood and blood components, somatic cells, gene therapy, tissues, and recombinant therapeutic proteins. They can be composed of sugars, proteins, or nucleic acids or complex combinations of these substances, or they may be living entities such as cells and tissues. Biologics are isolated from a variety of natural sources—human, animal, or microorganism—and may be produced by biotechnology methods. From a practical point of view, drugs entering the market require the filing of a New Drug Application (NDA), whereas biologics require the filing of a Biologic License Application (BLA).

Drugs

Small molecules are defined as carbon-containing compounds that usually have a molecular weight of less than

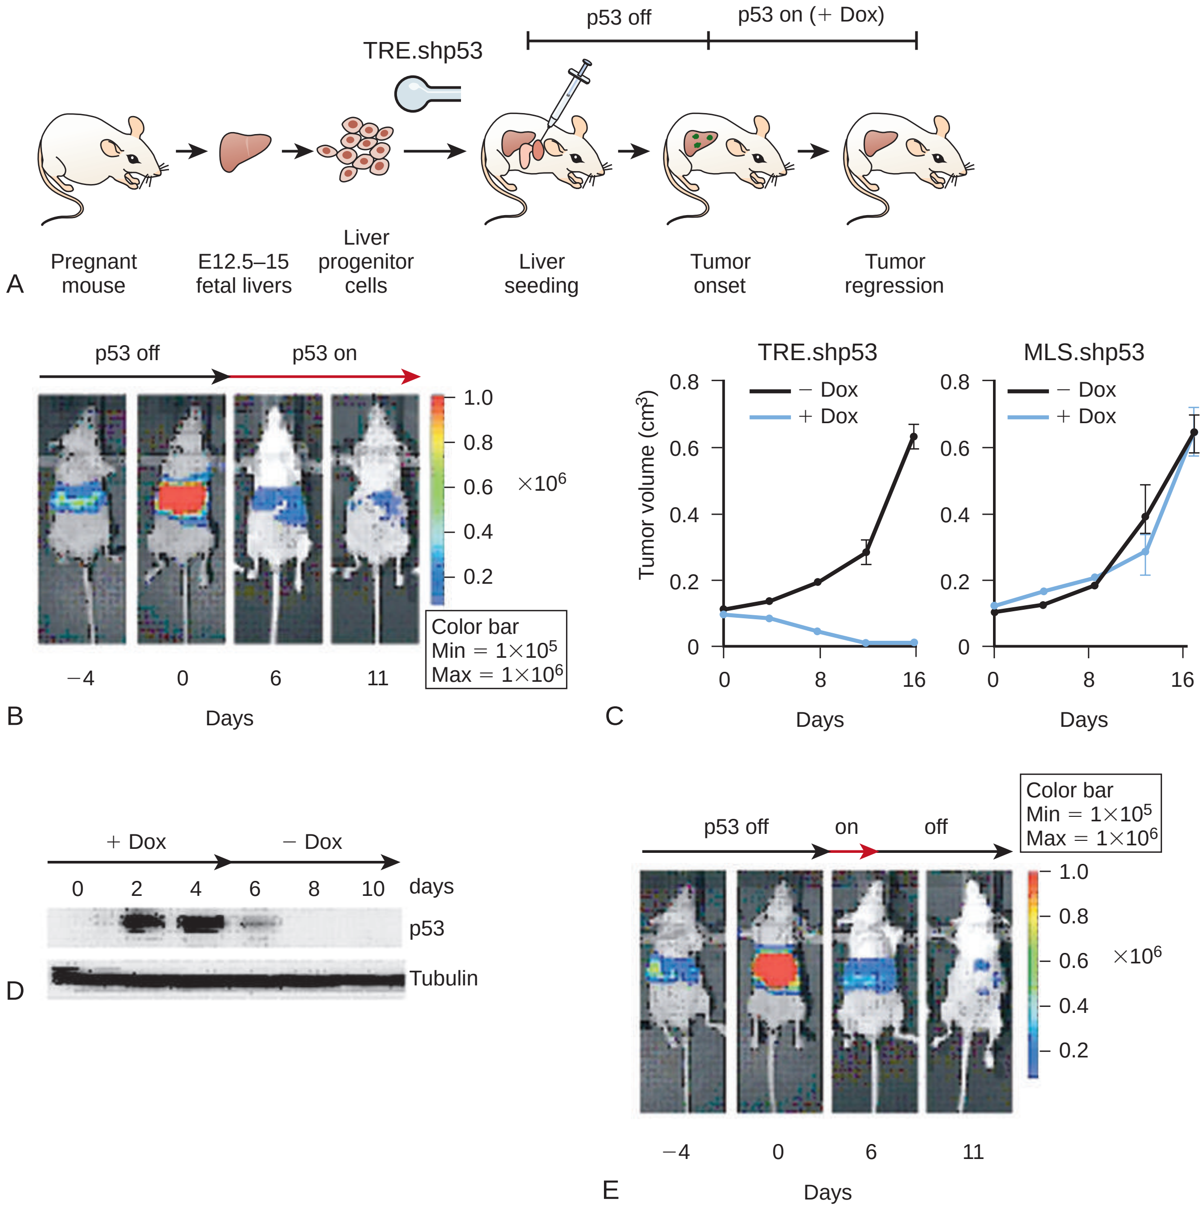

Figure 44-2 Reactivation of p53 results in liver tumor regression. **A,** Embryonic liver progenitor cells were transduced with a tetracycline-regulatable p53 shRNA (TRE.shp53), tTA, and H-rasV12. After onset of liver tumors, p53 expression could be restored by doxycycline (Dox) treatment. **B,** Reactivation of p53 leads to rapid tumor regression. Tumor-bearing mice were treated with Dox starting at day 0 and imaged at the indicated time points ($n = 9$). **C,** Subcutaneous tumors derived from ras-transformed liver progenitor cells with tet-off shRNA (TRE.shp53) or a nonregulatable shRNA (MLS.shp53) were grown in nude mice. Values represent mean s.d. ($n = 4$). **D,** p53 reactivation is reversed by Dox withdrawal. Protein lysates from liver progenitor cells pulse-treated with Dox for 4 days were immunoblotted for p53. **E,** Representative mice ($n = 6$) as in **B** were pulse-treated with Dox for 4 days and imaged at the indicated time. *(Modified from Xue, et al: Senescence and tumour clearance is triggered by p53 restoration in murine liver carcinomas.* Nature *445:656–60, 2007.)*

2000 g/mol. These small organic compounds have the advantage of purity, high permeability into target cells, ease of manufacturing, and stability, and they remain the primary class amenable to oral delivery. However, disadvantages include insufficient selectivity resulting in off-target toxicity, challenges with poor bioavailability, and challenges with metabolism of the molecule. Over the last decade synthetic methods have been developed for producing a diversity of chemical structures, either by using directed medicinal chemistry approaches or by using combinatorial chemistry, the synthesis of numerous organic compounds by combining variations of each of the building blocks that make up the compounds.[98] Similarly, there has been the elaboration of a diverse set of methods for identifying the initial small-molecule hits against a desired target. High-throughput screening involves the in vitro assay of target activity against chemical libraries. In silico screening can be used to dock millions of compounds into known or modeled three-dimensional structures of a given target. Fragment-based screening uses either

radiographic or nuclear magnetic resonance–based structural approaches to identify very-low-molecular-weight fragments that can interrogate the binding surface of a new target.[99] Finally, target-specific cell-based screens can be used to identify cell-penetrant small molecules perturbing a target-specific reporter or phenotype.

Natural products have been important in drug development and have played a dominant role in cancer therapy.[100] Approximately three fourths of the current anticancer drugs are natural products or derived from natural products.[101] The chemical diversity of natural products complements that of synthetic libraries. As a result of a long evolutionary process, natural products tend to be sterically complex with greater diversity of ring systems compared with synthetic and combinatorial libraries.

Natural products are classified according to shared scaffolding elements and can be divided into several structural classes, such as terpenes, alkaloids, polyketides, and nonribosomal peptides. The building blocks for the natural products are most often monomeric components of primary metabolic pathways that are then shunted into secondary metabolic pathways. Plants and soil microbes are traditional sources of natural products with new sources, such as fungi and marine life (e.g., sponges and algae), under active exploration.[102]

Drug development with natural products may have specific advantages to that of synthetic molecules. The complexity of natural products may lead to greater specificity. In addition, unanticipated activities may be discovered that would be difficult to engineer into a small molecule. For example, rapamycin (derived from a soil fungus from Easter Island [Rapa Nui]), creates a novel protein-drug-protein interaction between the protein FKBP12, rapamycin, and the mTOR kinase, resulting in an exquisitely selective inhibition of mTOR.[103,104] However, although the natural products have been developed into very successful drugs, there are several disadvantages to these libraries. First, natural product extracts are generally impure, and hence identifying the active compound can be difficult. Second, the synthesis of these compounds in production level quantities for medicinal purposes can be challenging. Third, subsequent optimization of the lead natural product can be difficult in the absence of a complete in vitro synthesis of the relevant natural product. New high-throughput strategies are under development to tackle roadblocks to the use of natural products for medicinal purposes.

Antisense oligonucleotides are single strands of short deoxynucleotide sequences (18-21 oligomers) that bind to target mRNA sequence by Watson-Crick hybridization and induce transcript destruction. They interact with the target transcript with sequence specificity and inhibit production of the target protein by several potential mechanisms. First, they activate endogenous nucleases, such as RNAse H, which then cleave the RNA strand of an RNA-DNA heteroduplex. A second potential mechanism of antisense activity is a noncatalytic effect with steric inhibition of the translational machinery with induction of translational arrest and inhibition of protein synthesis. A third mechanism is interference with normal RNA splicing, resulting in the inhibition of specific splice variants. Antisense therapeutics held the promise of pharmacologically inhibiting targets that had been intractable with small molecule approaches. In theory, virtually any gene can be targeted with antisense approaches with an expectation of high target selectivity. However, the development of antisense therapy has faced many challenges, including poor solubility, limited intracellular uptake, and rapid degradation. To overcome these issues, subsequent antisense therapy focused on chemical modification of the backbone to which the nucleoside bases are attached.

Despite these efforts, the utility of antisense therapy for cancer has been disappointing. However, there have been some clinical responses seen in trials. Oblimersen (Genasense), a phosphorothioate antisense therapy targeting BCL-2, has shown some activity in patients with heavily pretreated chronic lymphocytic leukemia (CLL).[105] Furthermore, recent data from a randomized phase III trial for patients with relapsed or refractory CLL comparing fludarabine plus cyclophosphamide with or without oblimersen demonstrated an increase in complete response and nodular partial response in patients in the oblimersen arm, particularly for those patients with fludarabine-sensitive disease.[106,107]

RNA interference (RNAi) is a more recent approach to nucleic acid–based therapy. Similar to antisense therapy, RNAi may have therapeutic application, particularly for targets that have been considered intractable by traditional drug discovery approaches. RNAi is a double-stranded RNA (dsRNA)–induced mechanism of gene silencing naturally occurring in plants and animals. Over the last few years, it has become possible to target virtually any gene in the genome for knockdown with small, dsRNA gene-silencing by using siRNAs or expressed shRNAs. The RNAi pathway is hypothesized to have evolved early in eukaryotes as a protection against viral and genetic pathogens. Double-stranded RNA viruses and genetic elements are subject to RNAi-dependent gene silencing as a means of cell-based immunity. Furthermore, endogenously expressed shRNAs may regulate gene expression during development through the RNAi pathway.[89,90] If exploited as a potential cancer therapy, RNAi has the potential advantages of (1) relative specificity for a particular gene target, (2) efficiency with the potential to achieve more than 90% knockdown, and

(3) widespread applicability with the potential of targeting any gene in the human genome. Unlike antisense oligonucleotides, RNAi takes advantage of a naturally occurring cellular mechanism for gene silencing.

As in the case of oligonucleotides, there are impasses to the development of RNAi-based therapies, including the difficulty of delivering large nucleic acid molecules to intracellular targets in humans. Unmodified siRNAs have a short half-life in human plasma and are rapidly excreted by the kidneys. Furthermore, to have activity the siRNA or shRNA must reach the cytoplasm of the targeted cell, and naked siRNAs are not efficiently taken up by mammalian cells unaided. One method of delivering shRNA that is commonly used in the laboratory to develop stable knockdown is the use of viral vectors. However, with viral vector delivery, there remains significant concern regarding insertional mutagenesis, carcinogenesis, direct cellular toxicity and short-lived on-target effects.[108-111] Other nonviral methods of delivery are actively under exploration. One possibility is to chemically modify the siRNA to increase its stability with modifications such as locked nucleic acid (LNA) residues[112,113] or phosphorothioates.[114] A second approach to increase the stability of the siRNA is to package it in liposomes[115] or other nanoparticles such as the cationic polymer polyethylenimine[116] or to use cholesterol modifications.[117] These packaging systems can also be modified to contain tissue-specific homing signals, such as the attachment of specific antibodies. Despite the problems with delivery and stability of RNAi, novel therapeutics using RNAi have entered clinical trials for multiple diseases.[118-120]

Biologicals

Antibody therapy with monoclonal antibodies (Mabs) is an increasingly important mode of targeted therapy for cancer. Early attempts at antibody-based therapy with murine Mabs were limited by immunogenicity, short half-life in humans, and poor ability to activate human immune effector mechanisms. With the evolution of recombinant DNA technology, it is now routine to create humanized Mabs. Recombinant antibodies with human crystallizable fragments (Fc) regions are much less immunogenic in humans than murine Mabs and can facilitate activation of immune effector mechanisms. Thus recombinant Mabs may have a dual mechanism of anticancer activity secondary to the specificity of epitope targeting with the antigen-binding fragment (Fab) and the recruitment of immune effectors with the Fc region. As a direct effect of the Mab variable domain binding to the target, they can have antagonist effects on receptor-ligand interactions and receptor-receptor interactions or agonistic effects on the target's biological activity. Second, if engineered to be of the immunoglobulin G1 (IgG1) subclass and to contain an Fc region, they induce immune effector function against I the target cell after their interactions with complement or with receptors for the Fc region, such as FcγR, a class of surface glycoproteins expressed predominantly on white blood cells. The Fc region interactions with FcγR can induce antibody-dependent cell-mediated cytotoxicity (ADCC), phagocytosis, endocytosis of immune complexes followed by antigen presentation, and release of inflammatory mediators.[121] Antibodies can be linked to chemical moieties with additional antitumor activity, such as in gemtuzumab ozogamicin, where an antibody to CD33 was conjugated to the antitumor antibiotic calicheamicin.

Box 44-7 **Advantages and Disadvantages of Antibody-Based Therapy**

ADVANTAGES

1. High-degree of specificity results in reduced off-target effects.
2. Pharmacokinetic properties are similar across different antibodies.
3. Spectrum of targets amenable to antibody-based therapy differs from that of small molecules.

DISADVANTAGES

1. Intravenous administration is necessary.
2. Preclinical in vivo studies are difficult to perform.
3. Neutralizing antibodies can develop.
4. Antibodies cannot access intracellular antigens.
5. Volume of distribution is limited by large molecular weight of antibody.
6. The cost of production is higher.

Bispecific antibodies: Whereas MAbs that are clinically effective usually recruit immune cells expressing an Fc receptor, T cells are notably FcR negative. To engage T cells in the antitumor response, bispecific antibodies (bsAbs) can be deployed. These are artificially designed molecules that bind simultaneously to two different antigens, one on the tumor cell, the other one on an immune cell, such as T cells, cross-linking tumor cells and T cells. For example, blinatumomab, a bsAb that directs T cells to CD19-expressing tumor cells, such as B-ALL and non-Hodgkin lymphoma (NHL) cells, has been demonstrated to have compelling activity in clinical trials, including complete responses.[122-124]

Antibody-based therapy has several advantages to small molecule–based therapy (Box 44-7). First, there is a high degree of specificity for the target of interest, resulting in reduced off-target effects. Second, pharmacokinetic properties are very similar from one antibody product to another, with the half-life of an infused antibody generally lasting 2 weeks. Unlike the case of small molecules, there is a consistent path for metabolism, thus eliminating a highly variable aspect of low-molecular-weight drug development. Third, the spectrum of targets amenable to antibody-based therapeutics is largely distinct from small molecules and includes large extracellular domains and secreted ligands that are otherwise "undruggable."

On the other hand, there are several disadvantages of antibody-based therapy compared with small-molecule therapy. Currently antibody-based therapies are generally delivered intravenously. A second disadvantage is that preclinical in vivo studies can be difficult to conduct.[125] The researcher must address whether the antibody in development will recognize the appropriate antigen in the animal model being tested. In some cases only primates conserve the relevant human epitope, limiting the selection of species available for toxicology studies. Efficacy studies, in particular against stromal or host factors, may require generation of a "murine equivalent" antibody, although equivalence is difficult to quantitate. The robust evaluation of host effector function elicited by an antibody and the role of this function in antitumor activity is also difficult to assess in the typical human tumor xenotransplant study in rodents. A third challenge with antibody-based therapy is that the patient can develop neutralizing antibodies to the therapy. This was particularly problematic with murine-based antibody therapy. Fourth, antibodies cannot easily gain access to intracellular antigens. Fifth, the volume of distribution of antibodies is limited by the large molecular weight, and tumor penetration is therefore a concern, at least theoretically. Finally, antibody-based treatment is generally more costly to produce compared with small-molecule therapy.

Cellular Adoptive Therapy

Most recently, cell-based biological products have also seen dramatic clinical responses. The transfer of autologous T cells modified to express chimeric antigen receptors (CARs) specific for the B-cell antigen CD19 has shown antitumor activity in low-grade B-cell malignancies and in refractory adult and pediatric B-cell ALL.[126,127] These exciting advances are discussed in more detail in Chapter 46.

Targeted Therapy: Lessons Learned from Adult Oncology

With rare exceptions, most drugs are first tested in adults before evaluation in children. This has been true for targeted agents as well. In the following section several examples of successful targeted therapies for the treatment of adult patients with cancer are briefly discussed, with an emphasis on particular lessons learned in the development and testing of these early agents.

Genetics Examples of Targeted Therapy

Treatment of Acute Promyelocytic Leukemia with All-*Trans*-Retinoic Acid. The successful treatment of patients with M3-AML (acute promyelocytic leukemia, or APL) with ATRA is one of the earliest examples of targeted therapy in the genetic class. This therapeutic discovery was serendipitous. The observation that myeloid blasts differentiate in response to retinoic acid derivatives preceded the discovery of the involvement of the retinoic acid receptor in the pathogenesis of APL.[128,129] ATRA treatment is one example of how discovery of a compound inducing a phenotypic alteration can lead to greater understanding of the mechanisms underlying the state change. By morphologic examination APL is characterized by a predominance of malignant hypergranular cells blocked at the promyelocyte stage of differentiation. At the molecular level a reciprocal translocation involving the *retinoic acid receptor α (RARα)* gene on chromosome 17q21 is invariably present. This translocation most commonly fuses *RARα* to the *PML* gene on chromosome 15q22. RARα is a hormone-dependent, DNA-binding, nuclear receptor transcription factor that can act as a transcriptional activator or inhibitor.[75,130,131] In the presence of physiologic amounts of retinoic acid, it normally functions as a transcriptional activator. Abnormal RARα fusion proteins function as transcriptional repressors, enhancing interactions with the corepressor complex.[132,133] Pharmacologic doses of ATRA appear to overcome the PML-RARα–induced transcriptional repression by dissociating the corepressors from PML-RARα and restoring normal ATRA-mediated myeloid differentiation.[134] Furthermore, the PML-RARα protein undergoes proteolytic cleavage in APL cells after ATRA treatment.[135] ATRA treatment increases the fraction of differentiated cells with functional characteristics of neutrophils, induces a mature membrane phenotype, inhibits leukemia cell proliferation, and ultimately induces apoptosis. Historically, APL was among the most fatal subtypes of AML. However, with the addition of ATRA to APL therapy regimens, the overall 2-year survival rate is more than 75%. APL now has the highest cure rate of the AML subtypes.[1,5,136]

The success of ATRA in the treatment of PML-RARα rearranged AML illustrates several important issues regarding targeted therapy. First, specific somatic rearrangements, such as PML-RARα, can be exploited with targeted therapy, and the specific underlying genetic event predicts response, not the phenotype. For example, other RARα rearrangements, such as PLZF- RARα, are associated with an APL phenotype. However, the PLZF-RARα fusion protein is associated with nuclear corepressor interactions that are resistant to ATRA therapy. Patients with the *PLZF-RARα* rearrangement are resistant to ATRA therapy.[137] A second important concept that emerges from the success of ATRA is that differentiation therapy is feasible for some malignancies. In general, terminally differentiated cells lose the capacity to divide and ultimately undergo apoptosis. This is indeed the case for APL cells treated with ATRA, which raises the possibility that such approaches may be more broadly applicable. A third important lesson from this example is that modulation of transcription factors is therapeutically feasible. Rearrangements involving transcription factors are a common event in the acute leukemias and in the pediatric solid tumors. Although well-characterized contributors to the malignant state, these transcription factor abnormalities have been considered "undruggable" or pharmacologically intractable because there is no obvious approach to inhibiting their function. However, ATRA therapy for the genetic lesion PML-RARα lends credence to the idea that these lesions can be targeted and that their modulation can have therapeutic efficacy. Finally, this example reinforces the importance of combination therapy not only for cytotoxic agents but also for targeted therapy. Although the majority of patients with APL in early trials achieved a complete remission with ATRA as a single agent, it was only in combination with conventional chemotherapy or arsenic trioxide that long-term cure rates were achieved.[6,136,138,7]

Imatinib in Chronic Myelogenous Leukemia. The development of imatinib for the treatment of CML stands out as the first example of a designed small-molecule inhibitor developed for the purpose of targeting an activated oncogene. Moreover, its dramatic single-agent activity in its initial phase I and II trials, along with the rapid path to registration, has provided the impetus for attempting to identify highly responsive patient populations during preclinical and early clinical development. In 1960 Nowell and Hungerford first detected the presence of the then-named *Philadelphia chromosome* in nearly all patients with CML.[139] This aberrant chromosome, resulting from the fusion of chromosomes 9 and 22, was subsequently shown to encode a fusion protein linking a gene of unknown function (*BCR,* or *breakpoint cluster region*) to the product of the *Abelson* gene—the cellular homologue of an oncoprotein activated by the Abelson leukemia virus. The discovery that the *Abelson* gene product (ABL) could function as a protein tyrosine kinase and that the normal autoregulatory domain of ABL was replaced with coding sequences from BCR led to the idea that constitutive activation of ABL kinase activity was likely a causal genetic event in CML.[140-142] In animal models production of BCR-ABL was sufficient to induce both acute and chronic leukemia.[143] These data, along with the presence of a catalytic domain, made BCR-ABL kinase an attractive drug target. Based on these elements, a drug-discovery program was launched, culminating in the discovery and clinical testing of imatinib (Gleevec), a small molecule inhibitor of BCR-ABL.

In the initial phase I trial by Druker and colleagues, 83 patients with interferon-refractory CML were enrolled and treated with doses of imatinib ranging from 25 to 1000 mg per day. No MTD was reached, and nausea, myalgias, edema, and diarrhea were the most frequent side effects. Remarkably, at a dose of 140 mg or higher, all patients had a hematologic response. At doses of 300 mg per day or greater, 53 of 54 patients had complete hematologic responses, 17 had major cytogenetic responses, and 7 had complete cytogenetic remissions.[144] Numerous subsequent trials demonstrated remarkable activity in CML and CML in accelerated phase, lymphoid or myeloid blast crisis or with Ph+ ALL in adults, including complete molecular responses.[144-148]

On the basis of these data, imatinib became the gold standard for first-line therapy of CML. Nonetheless, resistance to imatinib does occur. In vitro experiments conducted by using randomly mutagenized *ABL* cDNA libraries inserted into sensitive CML cells revealed that a defined spectrum of mutations in the *ABL* gene itself could preserve kinase activity but could disrupt binding to imatinib.[149] More important, sequencing of the *ABL* kinase domain in patients relapsing on imatinib revealed a similar spectrum of mutations in patient samples.[150,151] When these mutations were isolated and placed into ABL kinase constructs and re-inserted into sensitive CML cells in vitro, these mutant ABL constructs also rescued lethality induced by imatinib inhibition. These data, although initially concerning because of the potential for long-term control of the CML disease state, definitively demonstrated in humans the absolute requirement for ABL kinase activity in CML and closed the loop on the notion of a fully validated drug target. Moreover, the identification of such mutants provided the impetus for testing second-generation inhibitors that might overcome these resistance alleles. Here, two separate approaches were considered. First, although imatinib is a fairly selective inhibitor, it is not a particularly potent inhibitor. Because many mutations shifted the IC_{50} of the kinase activity, it remained possible that a more potent inhibitor might be able to overcome or prevent the emergence of these resistance alleles. Nilotinib is a second-generation inhibitor designed to target BCR-ABL and preserve the interaction with the inhibited form of the ABL kinase, the type II binding mode.[152] Nilotinib is more potent in biochemical and cellular assays of ABL activity and in phase I and phase II trials had significant activity in imatinib-resistant CML.[153] Nilotinib was later demonstrated to be superior to imatinib in patients with newly diagnosed chronic phase CML.[154] Dasatinib, initially developed as a src kinase inhibitor, binds to the "active" form of its kinase targets. Src kinases are highly related to ABL kinase activity, and in vitro testing showed that dasatinib had activity against imatinib-resistance alleles.[155] In phase I and II trials dasatanib has shown significant activity in imatinib-resistant patients.[156] Both dasatinib and nilotinib have gained FDA approval in imatinib-resistant patients with CML and in CML-accelerated phase and blast crisis. Ultimately, both drugs were approved for upfront therapy of patients with CML.[157]

Unfortunately, both nilotinib and dasatinib lack activity against a common but difficult to target *ABL* mutation, the T315I or "gatekeeper" mutation. This mutation creates a steric problem in the adenosine triphosphate–binding domain. This particular kinase domain conformation creates challenges in the drug design process. Notably, it has been difficult to make potent *and* selective inhibitors of this conformation inhibition. Recently, a drug with activity against the T3151 mutation, ponatinib, was granted accelerated approval by the FDA for the treatment of adult patients with chronic, accelerated, or blast-phase CML that is resistant or intolerant to prior tyrosine kinase inhibitor therapy or BCR-ABL–positive ALL that is resistant or intolerant to prior tyrosine kinase inhibitor therapy (Fig. 44-3).[158] However, the safety of this drug was later called into question secondary to concerns about drug-related arterial thrombotic events.[159,160]

Imatinib and Other Malignancies. Imatinib, in addition to inhibiting ABL kinase activity, also inhibits c-KIT and platelet-derived growth factor receptor (PDGFR). In preclinical cell line models of gastrointestinal stromal tumors (GIST), a tumor defined by frequent mutations in the *c-KIT* gene, efficacy of imatinib both in vitro and in murine xenograft models was demonstrated.[161] Based on these early preclinical findings, a patient with inoperable, recurrent, and treatment-refractory *c-KIT*-mutated GIST was treated with imatinib. After 4 weeks of therapy, the fludeoxyglucose-positron emission tomography scan showed a complete resolution of tracer uptake compared with the pretreatment scan, and over the ensuing 8 months the patient had a progressive diminution in the tumor volume.[162] Multiple subsequent studies demonstrated response to tyrosine kinase inhibitors in GIST,[163-166] and in 2008 the FDA granted accelerated approved for imatinib in the adjuvant setting for completely resected primary GISTs 3 cm and larger.

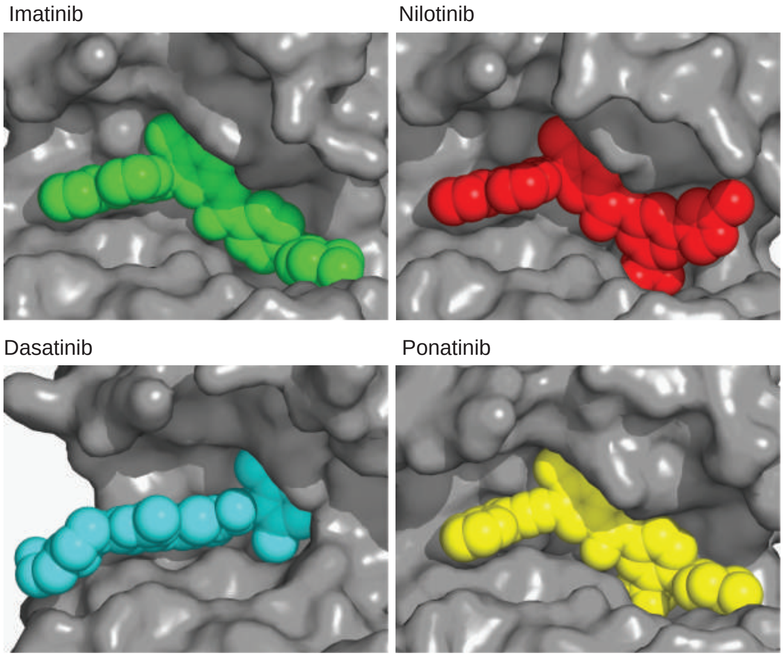

Figure 44-3 Abl inhibitors. Shown are representative structural images of the indicated small molecule inhibitors *(colored)* bound to the ABL kinase domain *(gray)*. Imatinib, nilotinib, and ponatinib are type II inhibitors and contain molecular components that occupy the hydrophobic pocket that is exposed when the kinase is in an "inactive" conformation. Dasatinib is a type I inhibitor and does not have extended interactions with the hydrophobic pocket and instead binds to the "active" conformation of the kinase. *(Courtesy Sandra Jacobson, Novartis Institutes for BioMedical Research, Emeryville, Calif.)*

The activity of imatinib against PDGFR or KIT has enabled clinical development in other diseases characterized as harboring specific genetic alterations activating these receptors. In the case of dermatofibrosarcoma (DFS) the majority of patient lesions harbor translocations between chromosomes 17 and 22 fusing the *PDGFB* ligand gene downstream of the *Col1a* promoter.[167] This leads to constitutive ligand production and receptor activation and sensitivity to imatinib in in vitro models, transplantable primary tumors from patients, and in patients treated with the drug.[168-170] In hypereosinophilic syndrome (HES) Schaller and Burkland report that empiric imatinib treatment of a patient with HES induced a complete and rapid remission of the disease.[171] Similarly, other studies revealed patients with HES responding to imatinib.[172] Gleich and colleagues reported the empiric treatment of five HES patients, four of whom had a prompt and sustained response to imatinib with a resolution of the eosinophilia.[173] The basis for these dramatic observations was uncovered in 2003, when Cools and coworkers reported the discovery of an intrachromosomal deletion that placed *PDGFRA* downstream of the promoter of the *FIP1L1* gene, resulting in constitutive upregulation of the receptor.[174]

The remarkable finding in the examples of the FDA-approval of imatinib for CML, GIST, dermatofibrosarcoma, and HES is that in each case a specific genetic event leads to constitutive activation of a molecular target of imatinib, and in each case a high degree of efficacy is achieved. Moreover, we have learned that efficacy is identified rapidly in selected patient populations, with dramatic responses even in phase I. We have learned that MTD does not necessarily set the appropriate effective dose, and, indeed, MTD end points were not reached in a number of the early phase I trials.

Dramatic Responses in Select Genotypes. With the success of imatinib for the treatment of patients with CML, a high bar was set for subsequent small-molecule kinase inhibitors. The possibilities that this targeted approach held for the poorly treated adult epithelial malignancies generated great excitement. The EGFR pathway is believed to be important in the development, maintenance, and proliferation of many malignancies, and EGFR is frequently overexpressed in epithelial solid tumors. For these reasons EGFR was an attractive target for small-molecule inhibition. Gefitinib (Iressa) and erlotinib (Tarceva), both orally administered tyrosine kinase inhibitors, were developed to bind competitively at the adenosine triphosphate pocket of EGFR, inhibiting autophosphorylation, and suppressing downstream EGFR signaling. Surprisingly, these EGFR inhibitors have been largely ineffective in the treatment of solid tumors with one exception: the treatment of a subset of patients with non–small cell lung cancer (NSCLC).[175-179]

After these initial clinical studies, numerous reports characterized the clinical predictors of tumor response (as opposed to survival) in patients. It soon became apparent that these patients frequently shared similar demographic features: a nonsmoking history, a well-differentiated adenocarcinoma histology, female sex, and Asian origin, although the underlying genetic reason for these response differences was not known.[178-180] One hypothesis was that expression levels of EGFR correlated with these clinical characteristics and hence response. However, these initial clinical trials failed to identify a correlation between receptor expression and clinical outcome.

Later, in 2004, two research groups independently identified a correlation between mutations in the tyrosine kinase domain of the EGFR and patient responders.[36,181] These *EGFR* mutations enhance ligand-dependent EGFR activation and sensitivity to gefitinib/erlotinib and are more common in nonsmokers, women, Asians, and patients with adenocarcinoma. Approximately 90% of these mutations occur in a few amino acids. Between 45% and 50% of mutations are in-frame deletions of exon 19 (codons 746 to 750), and 35% to 45% of mutations are missense mutation leucine to arginine at codon 858 (L858R) in exon 21.[182-185] Several studies have also reported that patients with EGFR mutant tumors have a longer survival when treated with EGFR small- molecule inhibitors compared with patients with wild-type EGFR tumors.[184,186-188]

This work highlights the importance of developing a molecular understanding of disease and response. The molecular characterization of EGFR abnormalities in NSCLC and their relationship to response to tyrosine kinase inhibitors have been illuminating for the clinical application of targeted therapy. More recently, the dramatic responses seen to B-RAF inhibition in patients with V600E *B-RAF*-mutant melanoma and to ALK inhibition in patients with *EML4-ALK* rearranged lung cancer underscores the critical role of matching tumor genotype with targeted drug therapy (Fig. 44-4).[189,190-192,193]

Lineage-Dependence Examples of Targeted Therapy

Several successful targeted cancer therapies capitalize on the lineage dependence of the tumor as exemplified by antibody-based therapy directed against cancers with hematologic lineage markers such as rituximab (Rituxan). As discussed in the subsequent sections, these therapies have the advantage of target specificity, with predictability of side effects based on the expression pattern of the lineage marker.

Rituximab Therapy for Non-Hodgkin Lymphoma. Rituximab (Rituxan) in 1997 became the first monoclonal antibody approved by the FDA for the treatment of malignancy (NHL). It is a chimeric, anti-CD20 monoclonal antibody composed of murine variable regions fused with human IgG1 heavy and κ light chains. CD20 is a transmembrane protein expressed on normal and malignant mature B lymphocytes[194] thought to be important in calcium transportation and to be involved in B-cell activation, differentiation, and growth regulation.[195] Rituximab binds to CD20 and depletes CD20-positive B cells in the circulation and in lymph nodes.

The first trials evaluating rituximab were in patients with indolent lymphoma, which has no curative therapy. The pivotal multicenter trial in patients with relapsed low-grade or follicular lymphoma demonstrated an overall response rate of 50% and a complete remission rate of 6%. These results were comparable with the best single-agent cytotoxic therapy for relapsed follicular lymphoma.[196] Rituximab has also been evaluated in combination with cytotoxic chemotherapy for patients with indolent B-cell lymphomas. One of the earliest studies, published in 1999, evaluated 40 patients with low-grade or follicular lymphoma treated with six cycles of CHOP (**c**yclophosphamide, **h**ydroxydaunorubicin, **o**ncovin, and **p**rednisone or **p**rednisolone) and rituximab (R-CHOP). The initial report suggested an additive benefit of

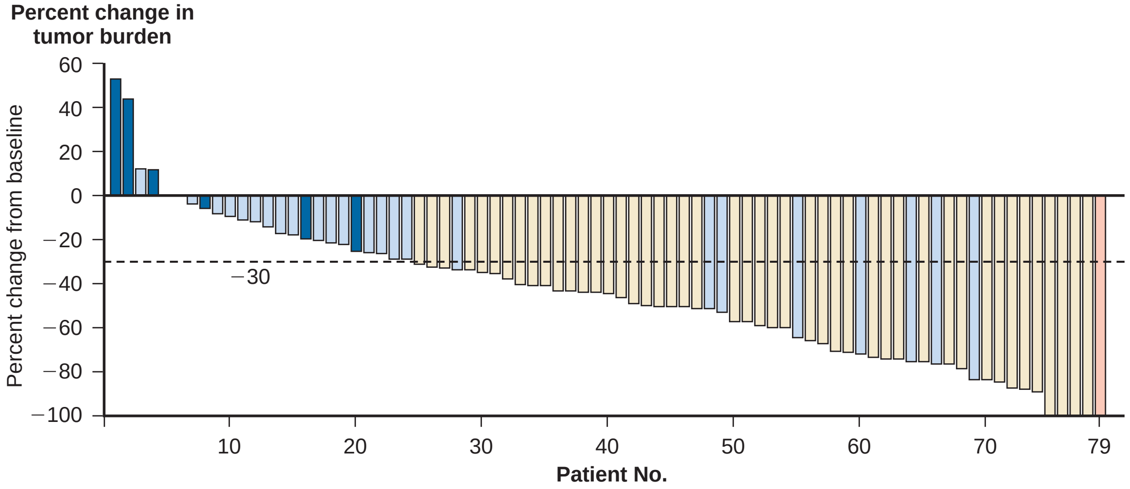

Figure 44-4 Response to ALK inhibition in patients with ALK-positive non–small cell lung cancer. Shown is the best response of patients with *ALK*-positive tumors who were treated with crizotinib, compared with pretreatment baseline. Numbers along the *x* axis indicate arbitrarily assigned patient numbers from 1 to 79. The *bars* indicate the percentage of change in tumor burden from baseline. *Black bars* indicate disease progression, *blue* stable disease, *yellow* partial response, and *orange* complete response. Four patients had complete resolution of their target lesions but were classified as having had a partial response on the basis of stability in nontarget lesions. Eight patients had tumor shrinkage of more than 30% but were classified as having stable disease either because confirmatory scans were not available by the data-cutoff point or early restaging was performed at 6 weeks after crizotinib initiation. The *dashed line* indicates a tumor reduction of 30% from baseline, the minimal percentage of decrease that constitutes a partial response, according to Response Evaluation Criteria in Solid Tumors. *(Modified from Kwak, et al: Anaplastic lymphoma kinase inhibition in non-small-cell lung cancer.* N Engl J Med *363:1693–703, 2010.)*

rituximab with no additional toxicity when these two therapies are used in combination.[197] The overall response rate was 95%, and the complete response rate was 55% in the intent-to-treat group. One of the larger clinical trials of 428 patients with previously untreated, advanced-stage follicular lymphoma assigned to CHOP or R-CHOP demonstrated an overall response rate of 90% with CHOP and 96% with R-CHOP and estimated survival rate at 2 years of 90% and 95%, respectively.[198]

The combination of rituximab with cytotoxic chemotherapy has also been evaluated for aggressive NHL. In a randomized phase III study comparing CHOP with R-CHOP in elderly patients with diffuse large B-cell lymphoma, the rate of complete response was higher in the group receiving R-CHOP (76% versus 63%, $P = 0.005$). Furthermore, at 2 years both event-free and overall survival rates were higher in the R-CHOP arm, with no significant additional toxicity.[199] A randomized study of CHOP-like chemotherapy alone or in combination with rituximab in adult patients ages 18 to 60 years with good-prognosis diffuse large B-cell lymphoma demonstrated a 3-year event-free survival rate of 59% with chemotherapy alone versus 79% with the addition of rituximab and at 6 years of 56% and 74%, respectively.[200,201]

Thus R-CHOP is now considered the standard of care for the first-line treatment of CD20-positive diffuse large B-cell lymphoma and for CD20-positive follicular B-cell NHL in combination with chemotherapy. Rituximab is also indicated for the treatment of patients with relapsed or refractory CD20-positive low-grade or follicular NHL.

Host Track Example of Targeted Therapy

Bevacizumab and Colorectal Cancer. Angiogenesis plays an important role in tumor formation. Continued tumor growth is dependent on new blood vessels for the supply of oxygen and critical nutrients. Moreover, certain somatic and germline alterations, including those disrupting the function of the *von Hipple-Lindau (VHL)* tumor-suppressor gene, appear to act largely by triggering dysregulated hypoxic and angiogenic responses.[202-205] Over the last several years, numerous angiogenic growth factors have been characterized, including vascular endothelial growth factor (VEGF). VEGF is a member of a large family of dimeric glycoproteins acting as growth factors. It is essential for the normal development of blood vessels and is a growth factor for vascular endothelium.[206,207] VEGF binds to the transmembrane tyrosine kinase receptors VEGFR1, VEGFR2, and VEGFR3. In the malignant state VEGF secreted by the tumor or surrounding stroma leads to endothelial cell proliferation and migration. Because VEGF and its receptors play a critical role in tumor formation, progression, and maintenance, VEGF or VEGFR inhibition became a focus of targeted antiangiogenesis therapy.[208] Several approaches are in development, but the two with the most success thus far are (1) neutralizing antibodies that inhibit the binding of VEGF to its receptors and (2) small-molecule tyrosine kinase inhibitors that block downstream signaling from the VEGFR.

Bevacizumab (Avastin) is a recombinant, humanized monoclonal antibody that binds to VEGF-A, preventing its interaction with the VEGF receptors. It is believed that bevacizumab affects tumor vasculature by several mechanisms: (1) inducing regression of tumor vasculature, (2) normalizing the tumor vasculature, (3) inhibiting new blood vessel formation, and (4) preventing recruitment of progenitor cells from the marrow. It may also improve chemotherapy delivery by altering tumor vasculature and decreasing interstitial pressure.[209] Bevacizumab has been approved by the FDA for first- (2004) and second- (2006) line treatment of patients with metastatic colorectal cancer and the treatment of nonsquamous metastatic lung cancer, although it extends survival by less than 6 months.[210-214]

As with most of the targeted therapies, many of the side effects of bevacizumab were predictable. Some of the reported side effects include hypertension, proteinuria, arterial thromboembolic events, bleeding, poor wound healing, gastrointestinal perforation, and reversible posterior leukoencephalopathy syndrome (RPLS). Most of these side effects are predictable from the known activity of VEGF. For example, VEGF is a homeostatic factor for regulating blood pressure. Blocking of VEGF or VEGFR leads to increased vascular tension and thus problems with hypertension and RPLS. It is interesting to note that the side effects of VEGF inhibition are similar to the signs of preeclampsia and eclampsia (hypertension, proteinuria, and mental status changes), a disease in which soluble VEGFR-1, which antagonizes VEGF functions, has been implicated.[215,216]

Other VEGFR pathway inhibitor development has focused on inhibition of the kinase activity of the VEGF receptor. In December of 2005 the FDA approved the drug sorafenib (Nexavar), a small-molecule VEGFR inhibitor, for the treatment of patients with advanced renal cell carcinoma, and in January of 2006 the FDA approved the multitargeted inhibitor (including VEGFR and KIT) sunitinib (Sutent) for the treatment of patients with both advanced renal cell carcinoma and for patients with GIST who are intolerant of, or who have had disease progression with, imatinib treatment.

The "success" of bevacizumab for colorectal cancer is a humbling one for drug development. In reality, there is a long way to go when the successful drug extends overall survival by less than 6 months. In pediatric cancer care this would hardly be deemed a victory. However, many lessons have been learned from this experience. One is that antiangiogenesis-directed therapy can play a role in some disease treatments. A second is the continued importance of combination therapy, even for targeted therapy. Bevacizumab alone had very little activity. It was in combination with standard cytotoxic agents that a clinical benefit was demonstrated. Third, careful evaluation of targeted therapy benefits and toxicities may provide new insight into human disease.

Empiric or Synthetic Lethal

As described previously, classical chemotherapy is likely to exploit cancer-dependent states that are not fully understood. For example, microtubule inhibitors, such as the taxanes, specifically interact with protein components of microtubules and are efficacious in a number of cancers, although there is no current scientific rationale for their selective efficacy. A number of emerging targeted therapeutics target highly selective protein targets involved in diverse basic cellular processes and were elaborated according to specific synthetic lethal hypotheses.

Histone Deacetylase Inhibitors. Histone deacetylase (HDAC) inhibitors are an example of an empirically acting targeted agent. Transcriptional repression and transcriptional activation, at least in part, reflect the balance of histone modification of chromatin structures surrounding gene regulatory regions. Histone acetylation is of particular importance. In many cases transcriptional activators recruit histone acetylase activity to gene regulatory regions, whereas transcriptional repression complexes typically recruit HDAC to the same regions. In keeping with the notion that repression might underlie the function of oncogenic transcription factor translocations, HDAC enzymes are recruited to the critical promoters by various translocation partners, including RARα and ETO. These data provide a compelling rationale for the development and testing of HDAC inhibitors. In keeping with the underlying concept of synthetic lethality, it is possible to hypothesize an enhanced dependence on, or constitutive requirement for, HDAC enzymes by the aforementioned repressive oncogenes. Although the original therapeutic concept evolved from a link between leukemogenesis and transcriptional repression, a large array of proteins are now known to be modulated through acetylation at the hands of 11 related HDACs.[217] This will invariably create difficulty in elucidating the underlying therapeutic mechanisms linked to the anticancer activity now observed in the clinic with relatively broad-acting HDAC inhibitors.

An array of HDAC inhibitors targeting the major classes of HDAC enzymes are now in the clinic. The majority of these inhibitors have a core hydroxamate structure that sits deep in the enzymatic pocket, making contacts with a key coordinated zinc atom in the enzyme. The most advanced of these compounds, vorinostat (suberoylanilide hydroxamic acid [SAHA]), was approved for the treatment of cutaneous T-cell lymphoma (CTCL).[218] In initial phase I studies testing vorinostat, diarrhea, anorexia, dehydration, and fatigue were found to be the limiting side effects. Thrombocytopenia was also frequent.[219] Based on early evidence of efficacy in patients with CTCL, a phase II trial of vorinostat was conducted exploring three dose levels.[218] Eight of 33 patients achieved a partial response. A phase IIB multicenter trial was subsequently conducted. In this trial of 74 patients who had all progressed or relapsed on at least two prior treatment regimens, 30% achieved an objective response and 77% of patients had some measure of disease improvement. One patient achieved a complete response.[220] These data provided the basis for the FDA approval of vorinostat for CTCL in 2006.

Romidepsin (depsipeptide, FR901228, FK228), a natural product bicyclic depsipeptide originally isolated from a broth culture of *Chromobacterium violaceum,* was discovered to have potent transcriptional activation properties and to be a potent inhibitor of HDAC enzymatic activity.[221] In the early clinical experiences with romidepsin, in addition to the observed toxicities with HDAC inhibitors discussed previously, cardiac abnormalities were also reported.[222,223] In a phase I trial conducted in pediatric patients taking romidepsin, the dose-limiting toxicities were T-wave inversions and transient sick sinus syndrome, which were asymptomatic.[224] In phase II trials romidepsin was tested in patients with neuroendocrine tumors and in patients with metastatic renal cell carcinoma. The neuroendocrine study was terminated because of serious cardiac adverse events, including ventricular arrythmias and prolonged QTc.[225] In the renal cancer trial, prolonged QTc interval (two), grade 3 atrial fibrillation and tachycardia (one), and sudden death (one) were observed.[226] There was insufficient antitumor activity to warrant further development in these indications. A phase II trial of romidepsin in patients with CTCL reported an overall response rate of 38%.[227] In 2009 the FDA approved romidepsin for CTCL in patients who have received at least one prior systemic therapy. Similarly, panobinostat (LBH589), a synthetic hydroxamic acid–based small-molecule inhibitor that was specifically designed as part of a drug-discovery effort directed at producing a pan-HDAC inhibitor, has been demonstrated to have activity in patients with CTCL but also to have the potential liability of cardiac toxicity.[228]

It is clear from the summation of these emerging data that HDAC inhibition results in significant activity in CTCL, although the reason for this empiric observation remains obscure. HDAC inhibitors are now being tested more widely in other solid tumor and hematologic malignancies. The key to these studies will be the elucidation of effective yet well-tolerated dosing regimens.

NEW AND EMERGING OPPORTUNITIES IN PEDIATRIC CANCER

Targeted therapies have been introduced into the pediatric cancer therapeutic arsenal.[229] Thus far, nearly all of these agents have already been tested in the adult community. Several have had success in the pediatric setting where the potential target is shared by the phenotypically identical adult and pediatric tumor, such as ATRA for children with APL,[230,231] imatinib for BCR-ABL–rearranged CML[232] and ALL,[233] and rituximab for lymphoma.[234,235] There are many targets—those shared by both adult and pediatric malignancies and targets specific to pediatric cancers—not yet thoroughly explored with targeted approaches. In the following sections we will discuss these new and emerging targets and the special considerations in bringing targeted therapy to the pediatric setting (Box 44-8).

Special Considerations in Targeted Therapy Development for Children

Majority of Children with Cancer Are Cured

There are numerous special considerations in the development of targeted therapy for pediatric cancer. In contrast to adults with cancer, the majority of children with cancer will be cured of the malignancy, making the selection of pediatric patients for testing of new targeted

Box 44-8 **Special Considerations in Pediatric Targeted Therapy Development**

1. Most children with cancer are cured.
2. Pediatric cancer is rare.
   a. Market incentive is reduced.
   b. Clinical trial design and accrual are difficult.
   c. Limited number of agents can be reasonably tested
3. Toxicity may be specific to developmental stage.
4. Ethical considerations are more difficult.
   a. Informed consent for experimental therapy must be obtained.
   b. Informed consent for participation in biological study must be obtained.

therapies more challenging and raising the required level of activity necessary for "success." For example, in de novo pediatric pre–B-cell ALL, with cure rates greater than 80%, it is difficult to introduce a new targeted agent for fear of detracting from an already excellent cure rate by diluting curative agents. Although there are many interesting new targets emerging, such as *PAX5* and other genes important in B-cell developmental pathways,[236] it would be difficult to justify the inclusion of upfront novel targeted therapy in patients with this excellent outcome. Thus it is likely in the relapsed setting, or in de novo disease with poor outcome, that novel targeted therapies will undergo initial testing. If efficacy and safety are demonstrated, researchers may then consider incorporation into upfront clinical trials.

Pediatric Cancer Is Rare

A total of 1,660,290 new diagnoses of cancer and 580,350 cancer deaths are projected to occur in the United States in 2013.[237] In contrast, it is estimated that only 14,023 children in the United States younger than age 20 years were diagnosed with cancer in 2009, and 1964 died of cancer in 2009.[238] Hence pediatric cancers are quite rare compared with adult malignancies, and there is a reduced market incentive for pediatric-specific targeted drug development by the pharmaceutical industry. Furthermore, researchers have been understandably hesitant to test new drugs in children. For these reasons, there are virtually no drugs that have been developed specifically for pediatric malignancies. Even when a common target has been identified in adult and pediatric cancer, it may be years before a drug reaches a pediatric trial. Because pediatric cancers are rare, even with a drug in hand to test, clinical trials are difficult. A rare disease incidence means slow accrual of patients and necessitates large cooperative groups to power the trial with appropriate patient numbers. The limited number of patients also precludes testing of all possible new agents. New methods are needed to more rationally choose novel targeted agents for testing in children.

One national attempt to prioritize the selection of new agents for testing in children with cancer was the development of the Pediatric Preclinical Testing Program (PPTP) by the National Cancer Institute. This group is prospectively testing new agents against a panel of xenografts and genetic models of pediatric cancer, such as neuroblastoma, rhabdomyosarcoma, osteosarcoma, and ALL. The PPTP builds on earlier work demonstrating the ability of preclinical testing of new agents in rhabdomyosarcoma and neuroblastoma xenografts to predict in vivo activity in children with these malignancies.[239,240] The development of new genetically engineered models of pediatric cancer should also facilitate preclinical evaluation of targeted therapies and better prioritization of new agents for clinical trial, particularly for diseases such as Ewing sarcoma, for which no such model yet exists.

Developmental Considerations in Targeted Therapy for Children

Children may tolerate targeted therapies differently from adults secondary to age-specific differences in physiology that result in altered pharmacokinetics or to drug interference with critical developmental pathways. In normal development, vascularization of cartilage is prominent during embryogenesis and during periods of growth when neoangiogenesis occurs at growth plates.[241,242] Inhibition of VEGF signaling has been reported in animal models to result in thickening of the epiphyseal growth plates secondary to an expansion of the hypertrophic chondrocyte zone.[243,244] These findings have been attributed to a delayed vascular invasion of the epiphyseal growth plate with a subsequent reduced rate of chondrocyte apoptosis. Inhibition of VEGF signaling has also been reported to impair trabecular bone formation, induce dental dysplasia, and cause ovarian atrophy.[245] Although the animal data are concerning, the actual long-term effects of this class of drug on human children is unknown.

Ethical Considerations in Targeted Therapy for Children

The testing of drugs in children raises issues universal to cytotoxic and targeted therapies, as well as challenges more specific to targeted treatments. Adults can make informed decisions about the risk and potential benefit of experimental therapies and biological studies and actively participate in treatment decisions. Particularly for young children, however, true informed consent from the patients for experimental therapies cannot be obtained. Here it is the parent or legal guardian making decisions about participation in a trial. In light of this potential conflict of interest, special regulations have been instituted to afford additional protection to children. These include the Code of Federal Regulations, Part 46; Protection of Human Subjects, Subpart D; and the related FDA regulation, Part 50, Protection of Human Subjects, Subpart D. These regulations outline allowable research in children based on the risk to the child, potential benefit to the child or other children, and alternative therapies. In the testing of targeted therapies, pharmacodynamic studies with sampling of tumor tissue before and after therapy initiation become more critical. For obvious reasons these studies can be difficult to perform with the current regulations, particularly for solid tumors or brain tumors. In general, tissue collection in children for the purpose of biological studies must be considered no greater than a minor increase in minimal risk. Innovative methods are needed to evaluate pharmacodynamic response, such as new imaging technologies, and better methods are needed to assess surrogate tissues.

Emerging Genetic Targets in Pediatric Cancer

Significant progress has been made in our understanding of the pediatric leukemias and solid tumors. As such, numerous potential genetic targets have emerged over the past 10 years. In light of the excellent cure rates for some pediatric malignancies, it might be difficult to incorporate target-directed therapies associated with good outcome genetic lesions, such as *TEL-AML1* in pediatric ALL. In these early stages of targeted therapy for pediatric malignancies, the focus will likely be on lesions associated with poor outcome. In the following section we will discuss some of these genetic lesions with potential for therapeutic targeting.

FLT3 and the Acute Leukemias

Although much progress has been made in the treatment of childhood leukemias, patients with AML with mutations in the Fms-like tyrosine kinase 3 *(FLT3)* gene remain a high-risk group. FLT3 is a class III receptor tyrosine kinase that plays a critical role in normal hematopoiesis and shares structural homology with PDGFR, c-KIT, and CSF1R. Upon the binding of FLT3 ligand, wild-type receptors dimerize and become activated by phosphorylation, leading to activation of downstream signal transduction pathways. Mutations in *FLT3* can be identified in blasts from 30% of adult patients with AML with constitutive activation of the kinase resulting from internal tandem duplications (ITD) in the juxtamembrane domain or point mutations in the activation loop.[246] The *FLT3* ITD is present in 15% and *FLT3* point mutations in 7% of pediatric AML, and children with FLT3 ITD have a particularly poor prognosis.[247,248]

FLT3 has also been implicated as a target in pediatric patients with *MLL*-rearranged ALL. Gene-expression profiling studies comparing *MLL*-rearranged ALL with all other ALL and AML have demonstrated a unique expression profile for *MLL*-rearranged leukemia. *FLT3* is the gene most frequently overexpressed in *MLL*-rearranged leukemia compared with the other acute leukemias.[249,250] An initial study reported mutations in *FLT3* in approximately 15% of samples of *MLL*-rearranged ALL. All of these were point mutations in the activation loop, including mutations not previously reported in patients with AML (deletion of isoleucine 836). These mutations lead to constitutive activation of the kinase and increased sensitivity to small-molecule inhibitors of FLT3. Furthermore, *MLL*-rearranged lymphoblasts with high levels of wild-type FLT3 were sensitive to the FLT3 inhibitor PKC412.[251] Subsequent studies have reported an incidence of *FLT3* mutations in infant MLL samples ranging from 3% to 18%. These studies also confirmed increased expression of FLT3 in *MLL*-rearranged infant ALL compared with both infant and noninfant patients with germline *MLL*. Even in the absence of documented mutation, a high level of FLT3 expression was associated with FLT3 ligand independence and with increased sensitivity to the FLT3 inhibitor PKC412.[252,253] In addition to its role as a target in *MLL*-rearranged ALL, FLT3 is a potential target in children with T-cell ALL (T-ALL), particularly with early precursor T-ALL, and in children with hyperdiploid ALL, wherein *FLT3* mutations have been reported.[253-257]

Several FLT3 inhibitors have been tested in clinical trials for adults with AML.[258-263] Most of the early trials testing these compounds have had some transient responders with decreased peripheral blood or marrow blasts, and the compounds have generally been well tolerated. However, very few patients enter a complete remission, and the majority of patients eventually progress. The high rate of initial response failure, as well as the development of progressive disease despite an initial clinical response, has tempered enthusiasm for FLT3 inhibitors in AML.[264] There are several possible explanations for the lack of dramatic clinical responses, including issues related to pharmacology and the failure to achieve sustained, complete inhibition of FLT3.[265,266] Another explanation is the acquisition of resistance mutations in *FLT3* itself. Indeed, the newer drug quizartinib (AC220), with greater potency and sustained inhibition of FLT3, has had promising initial results in clinical trials.[267] Moreover, point mutations within the kinase domain of *FLT3*-ITD, conferring quizartinib resistance, were recently reported.[268] This finding is similar to the emergence of *BCR-ABL*–resistance mutations in patients with CML treated with imatinib. Significantly, this study provided gold-standard validation that FLT3-ITD is an oncogenic driver of AML.

The clinical study of FLT3 inhibitors in children with leukemia is ongoing. A phase I trial testing the multikinase inhibitor sorafenib, with activity against FLT3, in children with refractory solid tumors and leukemia, was reported by the Children's Oncology Group (COG).[269] This trial established a recommended phase II dose of sorafenib for children with leukemias. Rash, diarrhea, and liver enzyme elevation were the most common sorafenib-related toxicities. Two patients with AML with the FLT3-ITD achieved less than 5% bone marrow blasts with 4 or 5 cycles of sorafenib. A second phase I trial evaluated the effects of sorafenib in combination with clofarabine and cytarabine in children with relapsed or refractory leukemia.[270] On day 8 of this trial, 10 of 12 patients demonstrated a decrease in blast percentage after sorafenib alone. After combination chemotherapy, six patients (three of these with FLT3-ITD) achieved a complete remission, two with FLT3-ITD had a complete remission with incomplete count recovery, and one patient with FLT3 wild-type had a partial remission. This trial also demonstrated downregulation of AKT, RPS6, and 4E-BP1 phosphorylation in leukemic blasts. Finally, there was another report of three patients with relapsed FLT3-ITD AML who achieved a sustained remission with sorafenib in combination with other cytotoxic chemotherapy.[271] Based on these encouraging initial results, there are now multiple ongoing trials to test the efficacy of FLT3 inhibitors in pediatric patients with leukemia.

JAK Mutations in Pediatric Leukemia

With the marked success of imatinib in the treatment of *BCR-ABL*-rearranged ALL in children (Fig. 44-5), there has been interest in the identification of other kinase abnormalities in childhood cancers, including leukemia.[233] Recurrent mutations in Janus kinases (JAKs) have

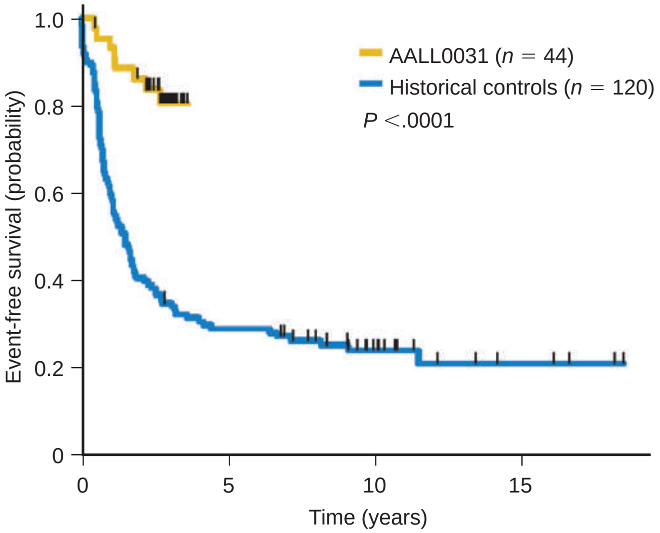

Figure 44-5 Early event-free survival in patients with Philadelphia chromosome–positive acute lymphoblastic leukemia treated with imatinib. Treated patients in cohort 5 ($n = 44$) were compared with patients previously treated on Pediatric Oncology Group protocols AL inC 14, 15, and 16 from January 1986 through November 1999 (n = 120). *(Modified from Schultz, et al: Improved early event-free survival with imatinib in Philadelphia chromosome-positive acute lymphoblastic leukemia: a children's oncology group study.* J Clin Oncol *27:5175–5181, 2009.)*

emerged as immediately targetable in a subset of pediatric patients with leukemia. JAKs phosphorylate substrates, including STAT proteins, on ligand binding to a type I cytokine receptor, leading to altered transcription of growth-enhancing and anti-apoptotic genes. Interest in targeting JAK2 was sparked by the finding of recurrent *JAK2* mutations (most frequently involving valine 617) in patients with myeloproliferative disorders.[81-83,272] Subsequently, activating mutations in *JAK2* and *JAK3* were reported in patients with AML and Down syndrome–associated acute megakaryoblastic leukemia[273,274] and in 18% to 28% of patients with Down syndrome–associated ALL.[275-278] In the case of Down syndrome–associated ALL, the mutations affect a highly conserved arginine residue (R683) in the pseudokinase domain of JAK2 and have been demonstrated to induce JAK/STAT activation and promote growth factor independence in BaF3 cells and response to JAK inhibitors.

In a subgroup of pediatric patients with poor-outcome ALL, a gene expression signature similar to that observed in patients with *BCR-ABL*–rearranged ALL was identified by genome-wide expression profiling in patients lacking the *BCR-ABL* rearrangement.[279] It was hypothesized that these *BCR-ABL*–negative cases might harbor other kinase abnormalities. Indeed, recurrent mutations in *JAK1*, *JAK2*, and *JAK3* were identified in approximately 11% of patients with high-risk B-precursor ALL (B-ALL), with mutations in *JAK2* being the most common.[280,281] As was seen in Down syndrome, the mutations in *JAK2* frequently involved the R683 residue. Mutations in *JAK2* are also frequently associated with overexpression of CRLF2 (cytokine receptor–like factor 2), a type I cytokine receptor subunit also referred to as *thymic stromal lymphopoietic receptor*.[282,283] Overexpression of CRLF2 has been linked to genomic rearrangement of *CRLF2* by way of a translocation of the immunoglobulin heavy chain (*IGH)* gene and by way of an interstitial deletion centromeric of *CRLF2* that results in a P2RY8-CRLF2 fusion.

There has been some controversy regarding the prognostic significance of *CRLF2* overexpression/genomic lesions and *JAK* mutations. In a study of 1061 pediatric patients with B-precursor ALL (both high risk and standard risk) treated on COG trials, it was found that only 50% of patients with high CRLF2 expression had *CRLF2* genomic lesions; the reason for high CRLF2 in the other 50% remains unclear. All *CRLF2* genomic lesions and nearly all *JAK* mutations were observed in samples with high CRLF2 expression. In this study high CRLF2 expression was associated with a very poor outcome in the high-risk patients with ALL but not in the standard-risk patients.[284] Thus targeting of JAKs, particularly JAK2, is of interest given its association with CRLF2 overexpression and poor outcome and the preclinical data supporting activity of JAK inhibitors in *JAK*-mutated ALL.[285] Clinical trials testing JAK inhibitors in pediatric patients are now ongoing.

ALK in Anaplastic Large Cell Lymphoma and Neuroblastoma

The discovery of the recurrent translocation t(2;5)(p23;q35) in anaplastic large cell lymphoma led to the cloning of *ALK*, a novel tyrosine kinase, as the key oncogene dysregulated by the gene fusion. Subsequently, *ALK* was found to be the transforming partner fused to the *EML4* promoter in approximately 4% of patients with adenocarcinoma of the lung[189] and to be activated by point mutations in neuroblastoma[286] and in inflammatory myoblastic tumors.[287,288] These data, in particular the findings in lung adenocarcinoma, triggered attempts to exploit this genetic information for therapeutic gain. Cells driven by the EML4-ALK fusion were shown to be sensitive to ALK inhibition in the original work describing the fusion event,[189] and it was known that crizotinib, originally developed as a MNNG HOS transforming gene (MET) inhibitor, was also a potent ALK inhibitor. Indeed, crizotinib showed significant preclinical efficacy in models of anaplastic lymphoma.[289] These data led to the rapid clinical testing of crizotinib in patients with lung adenocarcinoma tumors bearing ALK fusions. In the phase I testing of crizotinib, there was an overall response rate of 57%, including one complete response, and an additional 33% of patients achieved disease stabilization.[190] These data led to a randomized phase III trial comparing crizotinib with chemotherapy in patients with tumors harboring *ALK* translocations. In this trial the response rate to crizotinib was 65% compared with 20% in the chemotherapy arm (P >.001) and progression-free survival was 7.7 months in the crizotinib-treated patients compared with 3 months in the chemotherapy group.[290] Crizotinib received FDA market approval for the treatment of ALK-positive lung adenocarcinoma in August of 2011.

Crizotinib has recently been tested in pediatric patients with solid tumors enriched for those with ALK alterations.[291] The investigators enrolled 79 patients with a diversity of tumor types in children with an average age of 10.1 years. Crizotinib was well tolerated in children. Efficacy was marked in patients with tumor types known to harbor genetic alterations in *ALK*. In nine patients with anaplastic lymphoma, there were eight responders, including seven who responded completely and one whose disease remained stable. In addition, three of seven patients with inflammatory myofibroblastic tumors also responded to crizotinib, and the remainder all had stable disease. One patient (out of 11) with neuroblastoma also had a response. In summary, crizotinib is a promising agent in pediatric patients with these diseases.

In adenocarcinoma of the lung, treatment with crizotinib, although achieving marked efficacy, is eventually associated with the development of therapeutic resistance. In some cases this is accompanied by point mutations in the kinase domain creating specific resistance to the binding of the drug. Significantly, the most common de novo mutation in *ALK* observed in children with neuroblastoma is the *ALK* F1174L, a mutation reported to engender crizotinib resistance. Novel ALK inhibitors are now entering clinical trials in the hopes of both overcoming resistance and improving on the upfront therapy of tumors bearing genetic alterations in *ALK*. NVP-LDK378 is a selective ALK inhibitor that is more potent than crizotinib and has activity against some of the resistance mutations seen with crizotinib.[292] In a phase I trial of NVP-LDK378 in adults, both crizotinib-naïve and crizotinib-refractory patients were enrolled on ascending doses. Among 88 patients receiving doses greater than 400 mg daily, the overall response rate was 70% with a response rate of 73% in the crizotinib-refractory setting. NVP-LDK378 was well tolerated in this trial. On the basis of these data, the FDA granted Breakthrough designation to LDK387 in March 2013. Early clinical data for AP26113, a second-generation ALK inhibitor that also inhibits EGFR, have been reported. Here, among 18 evaluable ALK-positive patients there were 10 responses. In the 12 patients previously treated with an ALK inhibitor, eight patients responded (67%).[293] Finally, the ALK inhibitor CH5424802 showed a remarkable 93.5% response rate in Japanese patients with ALK-positive lung cancer not previously treated with crizotinib.[294] The evolution of this field has been rapid and promises to bring highly active ALK inhibitors to pediatric patients with *ALK*-mutant cancers, including anaplastic lymphoma, neuroblastoma, and inflammatory myoblastic tumors.

Mammalian Target of Rapamycin in Tuberous Sclerosis

Tuberous sclerosis is a rare disorder characterized by skin and mucosal manifestations, including angiofibromas and subungual fibromas and by central nervous system manifestations, including cortical tubers and a high incidence of seizures. Two notable tumors in this disorder are renal angiomyolipomas and subependymal giant cell astrocytoma (SEGA). Tuberous sclerosis arises from inactivating germline mutations in the tumor-suppressor genes *TSC1* or *TSC2*. The protein products of these genes, known as hamartin and tuberin, are negative regulators of the kinase known as mTOR, a critical regulator of cell growth and cell size. These cellular control mechanisms are primarily linked to the role of this protein complex in controlling protein translation. The regulatory interaction between the TSC genes and the mTOR pathway was first discovered in *Drosophila* organisms, wherein genetic interaction studies revealed that cells lacking tuberous sclerosis function were dependent on mTOR activity and the activity of the downstream kinase S6K for their aberrant growth characteristics. These studies suggested that rapamycin and other inhibitors of mTOR might have therapeutic benefit in patients with tuberous sclerosis.[295,296]

Rapamycin (sirolimus) is a natural product that acts as an allosteric inhibitor of mTOR. It does so by binding to FKBP12 and recruiting FKBP12 to the mTOR complex, creating an inactivated complex. Sirolimus was tested in a small study of patients with renal angiomyolipomas and pulmonary lymphangioleiomyomatosis, a disorder also caused by mutations in *TSC* genes. In this study five patients with renal angiomyolipomas had a tumor response over a 24-month period.[297] Everolimus is a derivative of rapamycin that has improved oral availability and demonstrated efficacy and market approval in a number of adult malignancies, including renal cell carcinoma, neuroendocrine tumors, and breast cancer. Everolimus has been tested in patients with tuberous sclerosis who have either angiomyolipomas or SEGA tumors. In a phase III randomized trial 35% of patients with SEGA (EXIST-1) responded to everolimus compared with 0% in the placebo control arm. Significantly, no patients in the treated arm progressed during the trial.[298] Similarly, in a phase III trial (EXIST-2) patients with angiomyolipoma had a response rate of 42% in the everolimus-treated arm compared with 0% in the placebo control arm.[299] On the basis of these data, everolimus was approved for use in these indications.

In earlier uncontrolled studies there was evidence of a reduction in seizure frequency that appeared independent of the effect on SEGA tumor volume reduction. This raised the possibility that ongoing dysregulation of mTOR signaling in the central nervous system could contribute directly to seizure frequency. To further understand these findings, a phase II study examining seizure frequency was conducted. Here, everolimus reduced the seizure frequency by 50% or more in 12 of 20 patients, and in total 17 of the 20 patients experienced seizure reduction with an overall median decrease of 73% ($P < .001$).[300] Together these data support the notion that everolimus is a highly effective agent in the treatment of SEGA and angiomyolipomas in children with tuberous sclerosis disease. In addition, everolimus might be effective in seizure control, although additional randomized data will be required.

RAS Pathway Activation and Inhibition in Childhood Cancers

Genetic alterations leading to activation of the RAS-MAPK pathway are frequent in pediatric cancers and precancer syndromes. Germline mutations in RAS pathway components, including *NF1, KRAS, NRAS, SHP2 (PTPN11), MEK2, SHOC2,* and *CBL,* result in a set of related disorders known collectively as “RASopathies.” These disorders include neurofibromatosis, Noonan syndrome, LEOPARD syndrome, Costello syndrome, cardiofaciocutaneous syndrome, and Legius syndrome.[301] Moreover, somatic activating mutations in *KRAS* and *NRAS* are also common in a diversity of pediatric tumors. Juvenile myelomonocytic leukemia (JMML), in both syndromic and nonsyndromic forms, appears to be a disease wherein RAS is activated in nearly all settings. In this disorder loss-of-function mutations in *NF1,* gain-of-function mutations in *SHP2,* and activating mutations in *RAS* genes all lead to constitutive RAS pathway activation.[302] In B-ALL, mutations in *NRAS* and *KRAS* are among the most common mutations found.[281,303] Similarly, *NRAS, KRAS, BRAF, SHP2,* and *NF1* are, in aggregate, frequently mutated in pediatric T-ALL.[257] In pediatric AML activating mutations in *NRAS* are seen in 10% of patients.[304]

Outside of the hematologic malignancies, recent discoveries highlight the role of alterations in BRAF, a key immediate downstream mediator of RAS signaling. In pilocytic astrocytoma duplications of the *BRAF* locus occurred in 28 of 53 patients (53%).[62] This genomic rearrangement results in a *KIAA1549-BRAF* fusion gene and constitutive activation of BRAF. Another surprising discovery was the finding of the oncogenic mutation *BRAFV600E,* most commonly seen in melanoma, in 57% of patients with Langerhans cell histiocytocis[63] and 50% of patients with the related disorder Erdheim-Chester disease.[305] In aggregate, both germline and somatic genetic alterations in RAS pathway components frequently occur in pediatric cancers, and these observations strongly support the rationale for testing RAS pathway inhibitors in these pediatric indications.

Emerging data from the targeted treatment of adult patients with melanoma suggest that we divide the therapeutic approach to the RAS pathway into two distinct categories: *BRAF* mutant tumors and those tumors with direct *RAS* mutation or with upstream genetic events (e.g., *NF1*) that lead to RAS activation. BRAF inhibitors have had dramatic efficacy in patients with melanoma bearing the V600E *BRAF* mutation.[306,307] These data have led to the market approval of vemurafenib and dabrafenib. In the NRAS or KRAS setting, however, BRAF inhibitors are not effective. In addition, the current generation of BRAF inhibitors all share the property of *activating* rather than inhibiting other RAF family members (CRAF or ARAF), especially in the setting of *KRAS* mutation. Hence although in the setting of *BRAF* mutation these drugs indeed turn off pathway signaling and lead to tumor regression, in settings of the wild-type RAS pathway or in the setting of *KRAS* mutation the drugs lead to pathway activation. Indeed, this so-called paradoxical activation results in a plethora of vemurafinib-mediated dermatologic side effects, including the induction of keratoacanthomas. In addition, at least one patient was found to have a *KRAS* mutant leukemia while on therapy for metastatic melanoma. Withdrawal of the vemurafenib led to partial regression of the leukemia,[308] suggesting that the drug was inducing tumor growth. These findings imply that the use of BRAF inhibitors is likely to be restricted to indications in which *BRAF* itself is mutated.

Studies attempting to elucidate the mechanisms of resistance to BRAF inhibition, both preclinical and clinical, have identified a number of alterations leading to therapeutic resistance primarily linked to activation of downstream signaling by MEK or ERK. These observations have led to combination clinical trials in which MEK inhibition has been combined with BRAF inhibition. Although many such trials are under way, the most advanced is the trial of dabrafenib and the MEK inhibitor trametinib. A phase II randomized study comparing this combination with dabrafenib alone found that median progression-free survival rate was increased from 5.8 months to 9.4 months. In addition, the response rate increased from 54% to 76%. Notably, the incidence of skin manifestations caused by "paradoxical activation" was significantly reduced, and hence the combination was well-tolerated.[309] These data suggest that the BRAF/MEK inhibitor combination will become a standard of care for *BRAF*-mutant melanoma.

Do these findings apply to pediatric patients? At the time of this review, phase I trials of dabrafenib and vemurafenib were ongoing in pediatric patients. Although results in pilocytic astrocytoma were not yet reported, Haroche and coworkers reported treating three patients with Erdheim-Chester disease with vemurafenib. For all three patients, treatment led to substantial and rapid clinical improvement, with tumor responses confirmed by imaging studies.[310] These exciting results support the notion that BRAF inhibition will find significant clinical utility in these disorders.

Therapeutic intervention in tumors driven by RAS or upstream activation event has proved more challenging. It has not been possible to develop direct inhibitors of RAS. Therefore current efforts are focused on interrupting the outputs of oncogenic RAS, including downstream effectors in the MAP kinase pathway, such as MEK, or downstream effectors in the PI3K pathway, such as PI3K or mTOR. In adult *NRAS*-mutant melanoma there is evidence for activity of MEK inhibitors, notably MEK162 which had a 20% response rate among *NRAS*-mutant patients in a phase II trial in melanoma.[311] In pediatric patients MEK inhibitor phase I trials are under way primarily in glioma, but on the basis of preclinical data there is also strong support for the clinical testing of MEK inhibitors in JMML.[312] As mentioned previously, mutations in the *NF1* gene result in activation of RAS. To date, most therapeutic interventions have focused on inhibiting mTOR downstream of RAS in patients with type 1 neurofibromatosis. Although clinical trials are progressing, no results have been reported. As in the case of *BRAF*-mutant tumors, it is likely that combination therapy will be required. In this case there is a rationale for testing the combinations of mTOR or PI3K pathway inhibitors and MEK inhibitors in pediatric disorders resulting from RAS activation.

Notch1 in T-ALL

With intensive chemotherapy the majority of children with T-ALL will be cured. However, ALL is still a leading cause of death from cancer in children, and intensive chemotherapy is not without toxicity. One important

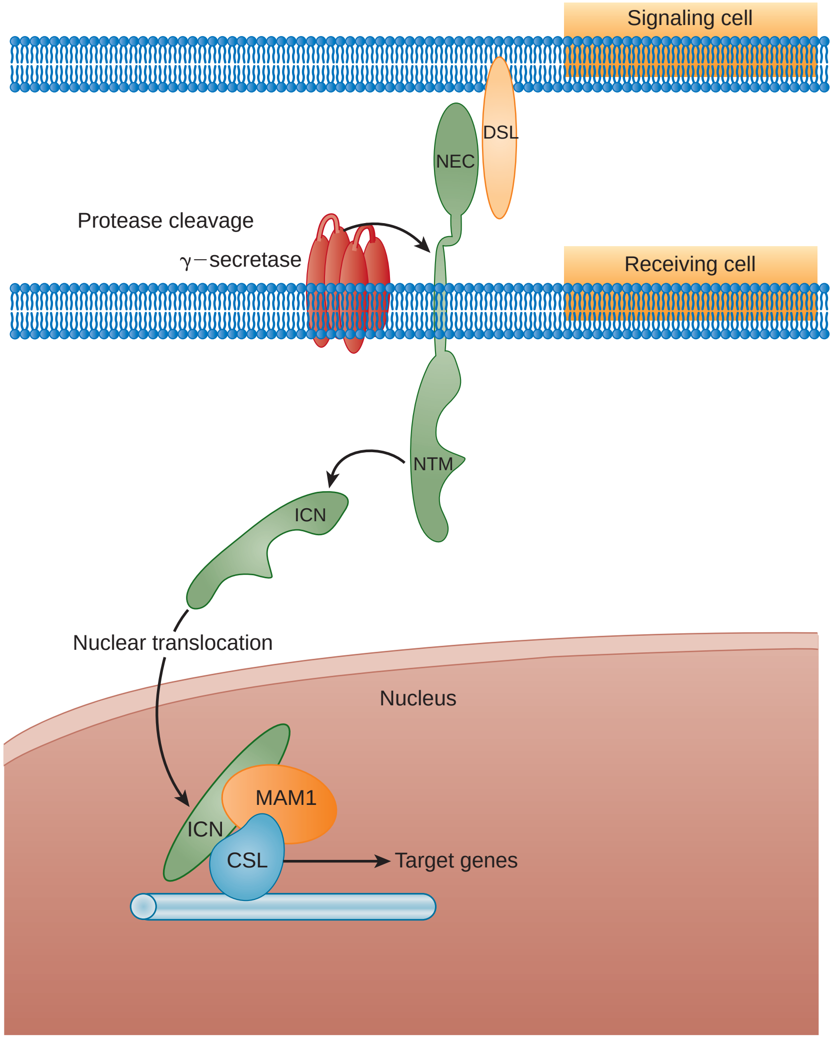

Figure 44-6 Notch1 signaling. Notch is activated by the binding of the ligands of the Delta-Serrate-Lag2 (DSL) family, which trigger a series of proteolytic cleavages. Notch receptors are cleaved by ADAM metalloproteases producing two noncovalently associated subunits, NEC and NTM. Next, cleavage by γ-secretase releases the intracellular domain of Notch (ICN), which translocates to the nucleus and forms a transcriptional activation complex with CSL and Mastermind-like (MAM1) cofactors. *CSL,* CBF1, Suppressor of Hairless, Lag-1; *NEC,* notch extracellular subunit; *NTM,* notch transmembrane subunit.

target in T-ALL is Notch1. *NOTCH1* encodes a transmembrane receptor required for T-cell differentiation and for the assembly of pre–T-cell receptor complexes in immature thymocytes (Fig. 44-6). Notch is activated by the binding of ligands of the Delta-Serrate-Lag2 (DSL) family that triggers a series of proteolytic cleavages, with the last step catalyzed by the γ-secretase complex, releasing the intracellular domain of Notch (ICN) into the cytoplasm, for subsequent translocation to the nucleus. Once in the nucleus, Notch acts as a transcriptional activator complexed with the DNA-binding protein CSL (CBF1, Suppressor of Hairless, Lag-1) and the transcriptional co-activators of the Mastermind-like family (MAML1).[313,314]

The oncogenic role of *NOTCH1* was first identified through its involvement in a rare (7;9) translocation in T-ALL.[315] Later, mutations in *NOTCH1* were discovered in 50% to 60% of T-ALL samples,[316,317] and *NOTCH1* mutations have also been reported in numerous murine models of T-ALL.[318-320] Enforced Notch signaling also induces T-ALL in mice.[321] In humans these mutations are activating mutations that involve the heterodimerization domain or the PEST domain of *NOTCH1* (or both), leading to constitutive activation or increased stability of the protein. Inhibition of γ-secretase is one possible approach to inhibiting Notch signaling. Initially, γ-secretase inhibitors (GSIs) were developed because of their potential therapeutic role in Alzheimer disease in cleaving amyloid precursor protein.[322] However, they were tested in Notch-dependent cancers in an attempt to block the production of the processed, nuclear form of Notch.[323] Many human T-ALL cell lines with Notch mutation showed a G0/G1 cell-cycle arrest in response to a GSI.[316] A Notch pathway inhibitor clinical trial with the GSI MK-0752 was opened in 2005 for patients with refractory T-ALL.[324] The drug was tolerated in a limited number of patients at doses below 300 mg/m^2. However, further dose escalation by continuous infusion was discontinued secondary to diarrhea. This gastrointestinal toxicity is thought to result from blockade of Notch1 and Notch2 in the gut, leading to intestinal secretory metaplasia, an increased number of goblet cells, and arrested proliferation in the crypts of the small intestine.[325] Because of the limited antileukemic activity in this trial and the severe gastrointestinal toxicity, studies were conducted to identify combination therapies with gamma secretase inhibitors (GSIs). One promising combination identified is GSI with glucocorticoids (GCs). This combination has been demonstrated to alleviate the gut toxicity by induction of cyclin D2 (CCND2), a cyclin associated with cell-cycle progression, and by the downregulation of Krüppel-like factor 4 (KLF4), a negative regulator of the cell cycle that is required for goblet cell differentiation.[326] It also potentiates the antileukemia effect of either drug given alone.[327,328] Alteration in the schedule of GSI delivery has also been evaluated, and a 3 day on, 4 day off dosing schedule was better tolerated.[329] Other approaches to Notch inhibition are being explored, including antibody-based targeting of the Notch1 receptor,[330,331] targeting of Notch ligands,[332] direct inhibition of the Notch1 complex,[333] and selective targeting of the maturation of the mutant receptor.[334]

Although the genetic and functional data to support targeting Notch1 in hematologic malignancy are compelling, and multiple approaches to targeting Notch may be feasible, there are still numerous challenges that lie ahead. One difficulty is the on-target side effects of inhibiting Notch, as discussed previously. Another concerning toxicity, reported in a recent trial performed in patients with Alzheimer disease, is the development of secondary malignancies because Notch pathway loss-of-function mutations have been reported in squamous cell carcinomas of the head and neck,[335,336] skin, and lung.[337] Here the hope is that intermittent dosing of the Notch inhibitor will mitigate this risk of secondary malignancy. A second concern in targeting Notch1 has been the largely cytostatic effect of Notch1 inhibition with GSIs and antibody-based therapy in preclinical testing. As in the case of cytotoxic therapy for cancer, targeted therapies will likely need to be used in combination with other drugs to achieve maximal clinical efficacy. In addition to the combination of GSI with GCs discussed previously, several studies support the combination of Notch1 inhibitors with inhibitors of the PI3K-AKT-mTOR pathway for T-ALL.[338,339] Notch pathway inhibitors have yet to be brought to pediatric testing.

Sonic Hedgehog Signaling and Medulloblastoma

Medulloblastoma is the most common malignant pediatric brain tumor. The sonic hedgehog signaling pathway, implicated in the pathogenesis of this disease, is a potential pathway for targeted therapy. Aberrant sonic hedgehog signaling was first implicated in the pathogenesis of medulloblastoma with the discovery of germline mutations in the sonic hedgehog (Shh) receptor gene *PTCH1* in patients with Gorlin syndrome (basal cell nevus syndrome) who have an underlying predisposition to develop medulloblastoma.[68,69] Heterozygous loss of *PTCH1* occurs in approximately 10% of sporadic medulloblastoma. Mutations in the downstream members of the hedgehog pathway, *Smo*, and *suppressor of fused (SUFU)*, have also been reported.[340-345] Furthermore, the hedgehog pathway is activated in approximately 30% of human medulloblastoma based on gene expression studies.[346]

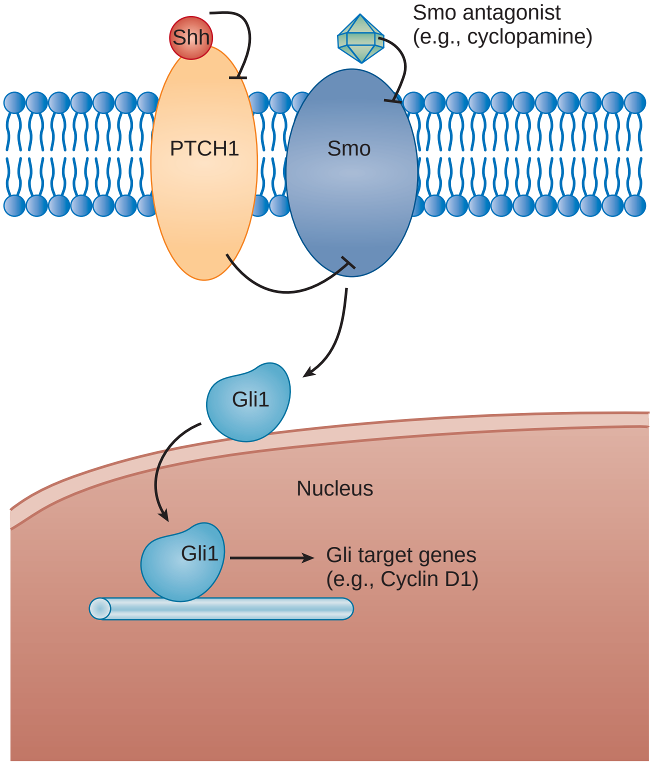

Figure 44-7 Hedgehog signaling. Patched (Ptch1) is a transmembrane receptor for the ligand sonic hedgehog (Shh). In the absence of Shh, Ptch1 inhibits Smo, a transmembrane protein with homology to G protein–coupled receptors. Upon Shh binding to Smo, this repression is relieved and signal is transduced through Smo to the nucleus, upregulating Gli1 transcription factors, which turn on a host of other transcriptional targets, including cyclin D1. *(Courtesy of Curtis Glavin and William Sellers.)*

PTCH1 is a transmembrane receptor for the ligand Shh (Fig. 44-7). In the absence of Shh, PTCH1 inhibits Smo, a transmembrane protein with homology to G-protein–coupled receptors. Upon Shh (ligand) binding to PTCH1, the repression is relieved and signal is transduced through Smo to the nucleus. This activity upregulates the Gli1 transcription factors, which in turn induces a set of transcriptional targets, including cyclin D1, PTCH1, and Gli1 themselves. SUFU appears to have a role in the repression of hedgehog signaling by interacting with GLI proteins in the cytoplasm and the nucleus.[347-349] The hedgehog pathway is critical for the development of the cerebellum and regulates the proliferation of granule neuron precursor cells in the cerebellum. Medulloblastoma is thought to originate from these immature granule cells.[343]

The goal of identifying inhibitors of the pathway began with the identification of cyclopamine, a plant-derived alkaloid from *Veratrum calcifornicum* initially described because of its causal role in the development of holoprosencephaly in livestock ingesting the plant.[350,351] Cyclopamine inhibits hedgehog signaling by binding to and inhibiting Smo, and this observation led to the therapeutic hypothesis that inhibition of Smo would reverse the transformed phenotype of Ptch-deficient medulloblastoma cells.[72] Indeed, cyclopamine inhibits the growth of medulloblastoma in vitro and in xenograft models of medulloblastoma.[72,352,353] Genetically engineered mouse models of medulloblastoma have been created with mice heterozygous for the *PCTH1* gene and null for *p53*. These animals develop medulloblastoma as early as week 2 and die from the disease by week 16.[354] In this animal model of medulloblastoma, a benzimidazole derivative, Hh-Antag691, with hedgehog-inhibitory activity via binding to Smo, led to a dose-dependent downregulation of hedgehog pathway members, decreased tumor burden, and increased disease-free survival rates in treated mice.[355]

These data led to the development and early clinical testing of Smo inhibitors in patients with basal cell carcinoma and medulloblastoma. Among the Smo inhibitors that have been in clinical testing are vismodegib (GDC-0449), sonidegib (NVP-LDE225), BMS-833923, PF04449913, LY2940680, saridegib (IPI-962) and TAK-441. Clinical trials of the latter two molecules have been discontinued. Vismodegib is the first Smo inhibitor and is currently approved in basal cell carcinoma on the basis of the tumor response rates in metastatic and locally advanced basal cell carcinoma (30% and 43%, respectively).[356,357] In the first report of its activity in medulloblastoma, a heavily pretreated patient with medulloblastoma had short-term tumor regression followed by progression at 3 months.[74] Analysis of this patient's tumor revealed an acquired point mutation in the Smo receptor likely mediating therapeutic resistance.[358] These data in aggregate suggested that medulloblastomas bearing a mutationally activated hedgehog pathway would be responsive to Smo inhibitors while also pointing out the potential problems of emergent resistance. Phase I testing of vismodegib led to a recommended phase II dose from this trial of 150 mg by mouth based on a maximal plasma exposure and pharmacodynamics reponse.[359] The activity of vismodegib in medulloblastoma is being evaluated in an ongoing phase II trial. Early results from the first 32 patients with refractory or relapsed medulloblastoma treated daily with 150 mg of vismodegib have been presented in preliminary form. Among 20 patients with sonic hedgehog–positive tumors, there were three with sustained response compared with no response among the patients with either no evidence of Shh activity or indeterminate tumors, and six patients remained on trial for longer than 6 months.[360]

Sonidegib (NVP-LDE225) is a potent Smo inhibitor with reasonable blood-brain barrier penetration as a feature of the molecule.[292] In phase I testing sonidegib was escalated from 100 to 3000 mg daily and also tried at 400 and 750 mg twice daily. Sonidegib was tolerated with doses as high as 800 mg daily. The MTD was defined by exposure-related creatine kinase elevations thought to be related to target-mediated effects on muscle. Gli1 mRNA, a marker of hedgehog pathway activity, was reduced by as much as 95% and 99% in skin and tumor biopsies. Preliminary evidence of activity was noted with one partial remission and one metabolic partial remission in medulloblastoma and one complete remission and four partial remissions in advanced basal cell carcinoma. Based on these data a phase II trial is being conducted in pediatric and adult patients with medulloblastoma in which post hoc evaluation of hedgehog activity is being conducted by using a five-gene hedgehog pathway mRNA signature. Preliminary results have been presented from 37 patients with medulloblastoma treated with sonidegib. In this cohort six patients responded (two complete remissions and four partial remissions) to sonidegib, and all responders were predicted to have hedgehog pathway–activated tumors. Of the remaining 31 patients, 29 were predicted to have hedgehog-inactive tumors and two were predictive to be hedgehog active. These latter two patients had stable disease. Based on the high concordance between the five-gene signature and patient response, this signature is now being used for patient selection to a randomized phase III trial comparing sonidegib with temozolamide in refractory or relapsed adult and pediatric medulloblastoma.[361] Taken together the aforementioned clinical data for vismodegib and sonidegib strongly support the notion that such inhibitors have significant clinical activity in hedgehog-activated medulloblastoma.

The hedgehog pathway is also thought to play a role in the maintenance of cancer stem cells. In particular, the preclinical data suggests that leukemia stem cells may be particularly dependent on hedgehog-pathway signaling.[362-364] To test this hypothesis the Smo inhibitor PF-0449913 has been tested clinically and found to have preliminary evidence of efficacy in AML; a complete remission with incomplete blood count recovery was noted in one patient, and five patients with AML had 50% or greater reduction in bone marrow blast counts. In addition, a major cytogenetic response with loss of the *T315I* mutation was observed in one patient with CML. These data suggest the Smo inhibitors may also find a role outside of tumor types driven by genetic mutations in the hedgehog pathway.

Transcription Factors and Pediatric Cancer

Abnormalities of transcription factors are a common genetic theme in the development of pediatric solid tumors, as well as leukemia. Often, the transcription factor is involved in a translocation rendering a new protein with aberrant transcriptional activity. Some examples of common transcription factor rearrangements are as follows: Ewing sarcoma *(EWS-FLI*, *EWS-ERG)*, alveolar rhabdomyosarcoma *(PAX3-FKHR, PAX7-FKHR)*, infantile fibrosarcoma *(TEL-NTRK3)*, ALL *(TEL-AML1, MLL* rearrangements, *E2A-PBX)*, and AML *(PML-RARα, AML1-ETO, CBFβ-MYH11, MLL* rearrangements). A second mechanism of transcription factor aberrancy is upregulation by amplification, such as amplification of *MYCN* in neuroblastoma and medulloblastoma. The high frequency of these abnormalities and the tumor cell specificity make these genetic lesions attractive targets. However, transcription factors have been considered "undruggable." Unlike enzymatic targets, such as kinases, transcription factors are not easily amenable to high-throughput screening assays. With the exception of the treatment of *PML-RARα*–rearranged APL, no current therapy directly targets these transcription factor abnormalities. Alternative approaches to small molecule discovery are needed. Technologies, such as RNAi, may facilitate therapeutic targeting of oncogenic transcription factors as better delivery methods are developed. Furthermore, these evolving technologies have enabled new methods for drug screening.

One approach to address the challenges to transcription-factor targeting exploits gene expression signatures. With this method gene expression signatures, defined by using genome-wide expression profiling, are used to identify different biological states. Then a small molecule library is screened with a low-cost, higher-throughput assay to identify compounds that induce the change in gene expression signature from "state A" to "state B." The gene expression signature definition, amplification, and detection are generic. Furthermore, a priori knowledge of a target is not needed. The gene expression signature serves as a surrogate for the biological state in question. The method is thus well suited for discovery of modulators of oncogenic transcription factors in which the mutant transcription factor's transforming mechanism is not known. One method developed, gene expression–based high-throughput screening (GE-HTS), used Affymetrix microarrays to define expression signatures of the two biological states of interest. From these high-complexity arrays, as many as 100 genes are selected as marker genes for each state. These signature genes are then amplified and detected with a high-throughput assay.[365,366] This approach was successfully used in a proof-of-concept experiment to identify inducers of AML differentiation. It was then extended to the modulation of transcription factors in an effort to identify small-molecule modulators of EWS-FLI in Ewing sarcoma, AML1-ETO in AML, and Notch1 in T-ALL.[334,367,368] GE-HTS provides an avenue for identifying tool compounds for the study of these genetic lesions and for identifying therapeutic leads. In fact, there are industry-based efforts incorporating gene expression fingerprints for drug discovery.

A second signature-based approach to address this problem uses a reference collection of gene expression profiles from cells treated with bioactive small molecules. This approach was initially demonstrated to be feasible in yeast with a pivotal study confirming that gene expression data could be used to functionally annotate small molecules and genes.[369] A pilot study next demonstrated the feasibility of this approach in human cell lines with the expression profiling of 164 distinct small molecule perturbagens, including many FDA-approved drugs and known bioactive compounds. Here the goal was to create an in silico tool (the Connectivity Map, or C-Map) for discovering the relationships among diseases, physiologic processes, and small molecule interventions.[370,371] One example pertinent to pediatric leukemia identified rapamycin as a small molecule candidate to reverse dexamethasone resistance in ALL.[372] In this example the C-Map was screened for molecules whose profile overlapped with a gene expression signature of GC sensitivity or resistance in ALL cells. The screen indicated that the mTOR inhibitor rapamycin profile matched the signature of GC sensitivity. Rapamycin was confirmed to sensitize ALL to GC-induced apoptosis, suggesting that the combination of rapamycin and GCs has potential utility in lymphoid malignancies. A clinical trial testing this hypothesis for pediatric patients with relapsed ALL is ongoing.

One approach to target the interface between proteins involved in transcriptional regulation uses peptides. One example is the use of specific peptide interference with BCL6 (B-cell lymphoma 6) transcriptional mechanisms in B-cell lymphoma.[373] Regulatory elements of the *BCL6* gene are frequently mutated in human diffuse large B-cell lymphoma, leading to sustained expression of BCL6.[374,375] This is thought to enhance B-cell survival, proliferation, and block differentiation. BCL6 possesses an N-terminal BTB/POZ (Bric-a-brac, Tramtrack, Broad complex/Poxvirus zinc finger) domain, and the BTB domain recruits the corepressors SMRT (silencing mediator of retinoid and thyroid receptors), NCoR (nuclear receptor corepressor) and BCoR (BCL6 corepressor).[376] The interface through which BCL6 recruits corepressor proteins was characterized with x-ray crystallography, and based on this structure a peptide inhibitor blocking the interaction of these proteins was designed.[377] This peptide disrupted BCL6-mediated repression and reactivated the expression of BCL6 target genes. Furthermore, in B-cell lymphoma cells positive for BCL6, the peptide caused apoptosis and cell cycle arrest. With improved methods of delivering peptides to cells, peptide therapy has become more feasible. One method fuses the peptide with protein transduction domains, which mediate receptor-independent cell penetration by binding the peptide to lipid rafts and triggering macropinocytosis.[378]

A second potential peptide-based approach to achieving this goal might use a reported stapled peptide technology. This approach has been applied to the activation of apoptosis by using a hydrocarbon-stapled BH3 peptide.[379,380] In contrast to the use of helical peptides to interfere with protein-protein interactions, which has been limited because of the loss of secondary structure in solution, susceptibility to degradation, and poor penetration of intact cells, the hydrocoarbon-stapled peptides proved to be helical, protease-resistant, and cell-permeable molecules that bound with increased affinity to target pockets. Hydrocarbon stapling of native peptides may provide a useful strategy for experimental and therapeutic modulation of protein-protein interactions, especially in disrupting transcription factor homodimers and heterodimers requiring extended helical interaction surfaces, as is the case for the MYC family.

Finally, multiple recent studies have used high-throughput in vitro screening of cancer cell lines to define genetic-, lineage-, and gene expression–based predictors of drug response. These studies focused primarily on adult cancers and involved the testing of a limited number of small molecules. Nevertheless, two of the most remarkable insights to emerge from those studies (discussed in greater detail later) were the discovery of marked sensitivity of Ewing sarcoma cell lines with EWS-ETS rearrangements to PARP inhibitors and the marked sensitivity of

MYCN-amplified neuroblastoma cell lines to BET bromodomain inhibitors.[381] These discoveries illustrate the potential power of comprehensive, pediatric cancer–focused screening to identify either compounds that directly interfere with aberrant transcription factors or synthetic lethal relationships in the presence of a transcription factor abnormality. Moreover, the potential of small molecule inhibitors of epigenetic regulators to alter aberrant transcriptional programs is revealed in the preclinical efficacy of BET bromodomain inhibitors in *MYCN*-amplified neuroblastoma tumors.

Emerging Lineage-Dependent Targets in Pediatric Cancer

Anti-GD2 and Neuroblastoma

Cure rates for children with high-stage neuroblastoma have improved with dose intensity of chemotherapy. However, even with double autologous stem cell transplantation, most children with stage 4 disease will relapse. For long-term survivors, therapy-related morbidity is high. Alternative approaches to cytotoxic therapy are clearly needed. One approach to targeted therapy for this disease has exploited the high-density expression of the neuronal lineage marker disialoganglioside, GD2, on neuroblastoma cells.[382] Several anti-GD2 monoclonal antibodies have been developed and tested in clinical trials.

One of the first was a murine IgG3 monoclonal antibody 3F8 directed at GD2. According to reports, 3F8 mediates neuroblastoma cell death by human complement activation and by activation of lymphocytes, monocytes, and neutrophils.[383-385] Initial studies testing 3F8 showed evidence of activity, particularly in children with minimal disease at the time of immunotherapy initiation.[386] Subsequent studies evaluated whether the addition of granulocyte-macrophage colony-stimulating factor (GM-CSF) to 3F8 would increase response by increasing the number of granulocytes and by priming effector cells for greater cytotoxicity. There were 45 patients with high-stage disease not in remission enrolled in the study.[387] Of the 15 patients with refractory bone marrow disease, 80% had a complete remission in bone marrow. Eleven patients were treated for recurrent neuroblastoma that was refractory to salvage therapy. Five of ten with marrow disease had complete remission in the marrow, but the one patient with soft tissue disease progressed. Additionally, the 15 patients treated for progressive disease did quite poorly, with all continuing to progress. The combination of GM-CSF and 3F8 was well tolerated, with the principal side effects of pain and rash. The authors concluded that the combination of 3F8 and GM-CSF was well tolerated and shows promise for treatment of minimal residual neuroblastoma in the bone marrow.

Another anti-GD2 antibody, 14.G2a, a murine monoclonal IgG2a antibody, has been tested in a clinical trial.[388,389] In an attempt to improve this antibody, a chimeric human/murine anti-GD2 monoclonal antibody (ch14.18) was developed and tested in phase I clinical trials, with some encouraging results.[390,391] This construct uses the 14.G2a variable region's heavy and light chains and human constant region genes for IgG1 heavy chain and kappa light chain. However, a large retrospective study of 334 assessable children older than 1 year of age (166 received ch14.18 consolidation treatment, 99 received 12-month low-dose maintenance chemotherapy, and 69 received no additional treatment) failed to demonstrate an advantage to ch14.18 in event-free survival or overall survival with multivariate analysis.[392] Similarly, an analysis of infants younger than 1 year of age failed to show a difference in outcome with ch14.18 consolidation therapy.[393]

Ch14.18 was also tested in combination with GM-CSF in a phase I study with manageable toxicities, including pain, urticaria, and emesis.[394] Testing was performed with humanized ch14.18 linked to IL-2 (hu14.18-IL2) with the hypothesis that IL-2 would augment activation of preexisting antigen specific T cells, enhancing destruction of tumor cells and activation of natural killer cells. A phase I trial demonstrated manageable side effects: hypotension, allergic reaction, fever, pain, marrow suppression, and blurred vision. Three patients out of 27 experienced some antitumor activity, with decreased tumor burden in the bone marrow.[395]

A landmark phase III trial evaluated ch14.18 administered in combination with interleukin-2 (IL-2) and GM-CSF and isotretinoin versus isotretinoin alone for patients after stem cell transplantation with a total of 226 eligible patients randomly assigned to each treatment group.[396] With a median duration of follow-up of 2.1 years, this immunotherapy was superior to standard therapy with event-free survival of 66 ± 5% versus 46 ± 5% and overall survival of 86 ± 4% versus 75 ±– 5%, and the trial was stopped early owing to efficacy based on event-free survival. This study reported that 52% of patients experienced grade 3, 4, or 5 pain; 23% capillary leak syndrome; and 25% hypersensitivity reactions, expected side effects attributable to antibody binding to GD2 on normal nerves, cytokine-mediated leak, and hypersensitivity to either antibody or cytokines, respectively. Immunotherapy was also more effective in patients with minimal, rather than high, levels of residual disease. Patients who had biopsy-proven persistent disease before entering the study were nonrandomly assigned to immunotherapy, and event-free survival for these patients was only 36% ± 10% at 2 years. Nevertheless, this study suggests the more routine use of lineage-directed immunotherapy for patients with neuroblastoma with minimal residual disease after stem cell transplantation.

Emerging Synthetic Lethal or Empiric Track: Targets in Pediatric Cancer

Insulin-like Growth Factor Receptor Signaling and Pediatric Solid Tumors

More than 10 years ago, the insulin-like growth factor-1 receptor (IGF-1R) signaling pathway was implicated in Ewing sarcoma. It has also been implicated in other pediatric and adult tumors.[397] With the evolution of small molecule inhibitors of receptor tyrosine kinases and the development of antibody-based therapy, therapeutic inhibition of this pathway has become a reality. IGF-1R is a heterodimeric tyrosine kinase receptor. IGF-1 and IGF-2, and to a lesser extent insulin, bind to IGF-1R, leading to receptor activation, autophosphorylation, and phosphorylation of downstream targets. The receptor is important for development, cell growth, transformation, and the prevention of apoptosis.

One early study demonstrated that IGF-1 mRNA was expressed in 90% of Ewing tumor samples positive for the EWS-FLI translocation. Furthermore, this work demonstrated that blockade of the IGF-1R with a monoclonal antibody inhibited serum free growth in a Ewing cell line.[398] Next, it was demonstrated that IGF-1R is essential for EWS-FLI transformation of fibroblasts and that expression of the EWS-FLI fusion may alter the IGF-1R signaling pathway.[399] In addition, the expression of insulin-like growth factor binding protein (IGFBP-3) is strongly induced with siRNA against EWS-FLI, and EWS-FLI can bind the IGFBP-3 promoter and repress its activity, suggesting that dysregulation of IGFBP-3 contributes to the development of Ewing sarcoma.[400,401] With the advent of inhibitors of IGF-1R, it was next demonstrated that small molecule inhibitors of IGF-1R, such as NVP-AEW541, a pyrrolopyrimidine derivative with selectivity for IGF-1R versus insulin receptor, had activity in vitro and in vivo models of Ewing sarcoma.[402,403] Furthermore, a dominant negative mutant IGF-1R inhibited tumorigenesis and induced apoptosis in Ewing sarcoma cells.[404]

In addition to Ewing sarcoma, IGF-1R has been implicated in numerous other pediatric solid tumors. One study reported inhibition of proliferation in several pediatric cancer–related cell lines (neuroblastoma, rhabdomyosarcoma, and osteosarcoma) with an antagonistic, monoclonal antibody (EM164) directed against IGF-1R.[405] Other evidence implicating IGF-related signaling in rhabdomyosarcoma, particularly for alveolar, includes upregulation of IGF-2 in cell lines, cooperation of IGF-2, and PAX3-FKHR, and inhibition of rhabdomyosarcoma growth with overexpression of IGFBP-6, an inhibitor of IGF-2.[406-408] In osteosarcoma, expression of IGF-1R has been reported in both canine and human cells.[409] In neuroblastoma the small molecule inhibitor NVP-AEW541 has had in vitro and in vivo activity,[410] and data suggest that IGF-1R expression may regulate metastases to bone.[411]

Initial phase I trials testing monoclonal antibodies against IGF-1R demonstrated tolerability of this approach in patients with sarcoma, with excitement generated about responses seen specifically in patients with Ewing sarcoma.[412-414] However, this initial excitement was tempered in subsequent follow-up trials wherein moderate activity has been observed. A phase I/II study of figitumumab, a fully human IgG2 monoclonal antibody against the IGF-1R, enrolled 106 evaluable patients with Ewing sarcoma in the phase II component of the trial.[415] Of these, 15 had a partial response (overall response rate = 14.2%) and 25 had stable disease. However, the median duration of response was only 4.7 months, and median overall survival was only 8.9 months. Another phase II study testing R1507, the fully human IgG1 monoclonal antibody against the IGF-1R, enrolled 115 patients with Ewing sarcoma.[416] For all patients the overall response rate was 10% with a 29-week median duration of response and a median overall survival of 7.6 months. This study identified patients with bone primaries as more likely to respond to antibody therapy compared with patients with extraskeletal sites. A third phase II study tested the fully human monoclonal antibody antagonist of IGF-1R, ganitumab, in patients with Ewing sarcoma and desmoplastic small round blue cell tumors (DSRCT).[417] In this trial, of the 35 evaluable patients, only two had an objective response for an overall response rate of 6%, although 49% of patients had stable disease.

Although the data suggest modest activity of anti–IGF-1R antibody therapy in a subset of patients with Ewing sarcoma, and possibly DSRCT, biomarkers of sensitivity have yet to be identified. The *IGF1R* gene is not commonly mutated in Ewing sarcoma, and although some studies have correlated IGF-1 serum levels with a longer median overall survival, neither serum IGF-1 nor tumor IGF-1R have been demonstrated to be associated with response to IGF-1R antibody therapy.[415,417-419] Identification of biomarkers of response and mechanisms of rapid resistance to IGF-1R therapy are critical next steps in determining the role of IGF-1R–directed therapy for patients with Ewing sarcoma. Moreover, the identification of highly efficacious combination therapies with IGF-1R antibodies is another active avenue of pursuit.[420]

Poly(ADP-ribose) Polymerase Inhibitors in Ewing Sarcoma

In an effort to uncover new biomarkers of drug sensitivity and resistance, several groups have screened large collections of genetically annotated cancer cell lines against hundreds of drugs.[93,94] Although well-known connections between genotype and chemosensitivity have been validated (e.g., BCR-ABL–positive cell lines are sensitive to multiple ABL inhibitors), new tumor vulnerabilities are emerging. For example, in a study conducted by Garnett and colleagues, 639 human cancer cell lines were screened with 130 drugs under clinical preclinical testing. Ewing sarcoma cell lines expressing EWS-FLI fusions were identified as highly sensitive to multiple structurally distinct PARP inhibitors, undergoing apoptosis in vitro.[94] Tumors harboring either *BRCA1* or *BRCA2* mutations have been demonstrated to have increased sensitivity to PARP inhibitors owing to defects in homologous recombination and reliance on alternative pathways to repair DNA damage that are targeted by these inhibitors. Ewing sarcoma tumors, however, have not been demonstrated to have genomic events involving *BRCA1* or *BRCA2*. Rather, these investigators confirmed that the presence of the EWS-FLI fusion engenders sensitivity to PARP inhibitors by demonstrating that mouse mesenchymal cells transformed with EWS-FLI were more sensitive to the PARP inhibitor olaparib than when they were transformed with FUS-CHOP. Expression of EWS-FLI in NIH3T3 cells also conferred greater sensitivity to this compound class compared with a control.

Although the precise mechanism of Ewing sarcoma cell line sensitivity to PARP inhibitors is still under consideration, a study by Brenner and colleagues suggests that EWS-FLI or EWS-ERG fusions themselves promote DNA damage.[421] In this study the authors report that Ewing sarcoma cell lines have DNA double-strand breaks induced by the expression of the EWS-ETS fusion and that treatment with PARP inhibitors potentiates this DNA damage. Moreover, they found that EWS-FLI enhances the expression of PARP in a positive feedback loop, and a synergistic response was seen when PARP inhibitors were combined with the DNA-damaging agent temozolomide in preclinical models of Ewing sarcoma. These initial preclinical observations were rapidly translated to phase I/II trials for patients with Ewing sarcoma, with results of these trials still pending.

BRD4 in Pediatric Cancers

Another example of the power of high-throughput in vitro screening of cancer cell lines to define genetic, lineage, and gene expression–based predictors of drug response is provided by the identification of the sensitivity of *MYCN*-amplified neuroblastoma cells to BET bromodomain inhibitors.[381] The BET family is composed of BRD2, BRD3, BRD4, and BRDT. All are defined by two N-terminal bromodomains sharing high levels of sequence conservation. BET family members are epigenetic "readers," which recognize covalent modifications of histone proteins or DNA.[422] One important modification associated with open chromatin, and thus transcriptional activation, is the ε-N-acetylation of lysine residues on histone tails.[423] Context-specific molecular recognition of acetyl-lysine residues is mediated by 61 diverse bromodomains, comprising 46 human proteins.[424]

The BET family member BRD4 has been reported to be a critical mediator of cell cycle progression and transcriptional elongation, functioning to recruit the positive transcription elongation factor b (P-TEFb).[425-427] BRD4 has been identified as a component of a recurrent t(15;19) chromosomal translocation in NUT midline carcinoma (NMC), resulting in the expression of the twin N-terminal bromodomains of BRD4 as an in-frame chimera with the NUT protein.[428] Functional studies in patient-derived NMC cell lines have validated the essential role of the BRD4-NUT oncoprotein in maintaining a proliferation advantage and differentiation block.[429]

Recently, multiple BET bromodomain small molecule inhibitors have been developed that displace BET bromodomains from chromatin by competitively binding to the acetyl-lysine recognition pocket. Not only have these molecules had remarkable preclinical activity in NMC, but they have also been shown to modulate the transcriptional function of MYC in several diseases, including AML, T-ALL, and multiple myeloma.[430-434] BET proteins bind to acetylated histone lysines and modulate transcription by recruiting transcriptional activators; MYC-regulated transcription is associated with increases in histone lysine acetylation. Unexpectedly, however, it was discovered that MYC itself is transcriptionally regulated by BET bromodomains.[431,432,434] In multiple myeloma cells JQ1 treatment leads to depletion of the MYC oncoprotein and downregulation of the coordinated MYC transcriptional program, leading to cell cycle arrest and senescence. This was associated with significant therapeutic responses in orthotopic xenograft studies as well as genetically engineered mouse models of multiple myeloma. Moreover, in AML, JQ1 treatment inhibited MYC transcription and promoted AML differentiation and response in a mouse model of MLL-rearranged leukemia,[432] and in ALL, BET inhibition targeted IL7R with prolonged survival in mice xenografted with primary human *CRLF2*-rearranged B-ALL treated with JQ1.[435]

An unbiased screen of a collection of 673 genetically characterized cancer cell lines was conducted to understand response and resistance to BET inhibition and to find new opportunities for therapeutic development. Neuroblastoma was identified as one of the most JQ1-sensitive diseases and *MYCN* amplification as the most predictive marker of sensitivity.[381] Subsequent studies revealed a strong correlation between *MYCN* amplification and sensitivity to bromodomain inhibition. Bromodomain-mediated inhibition of MYCN impaired growth and induced apoptosis in neuroblastoma and suppressed the MYCN pattern of gene expression. BRD4 knockdown phenocopied these effects, establishing BET bromodomains as transcriptional regulators of *MYCN*. BET inhibition conferred a significant survival advantage in three in vivo neuroblastoma models, including a primary human orthotopic xenograft and a MYCN GEMM, and this efficacy correlated with blockade of both MYCN and of MYCN target genes, providing a strong rationale for developing BET bromodomain inhibitors in patients with neuroblastoma. The preclinical evaluation of BET bromodomain inhibitors in other MYCN-driven malignancies, such as medulloblastoma, is ongoing.

BET bromodomain inhibitors have entered the clinic, with trials now ongoing in adult diseases. Indeed, investigators reported the safety of chronic administration of the BET inhibitor RVX-208 from a clinical trial to treat atherosclerosis.[436] Future trials are under development for pediatric malignancies.

EZH2 in Pediatric Cancer

Whereas some targets have emerged from high-throughput screening efforts, other pediatric cancer vulnerabilities have been uncovered through the detailed study of genetic models of specific diseases. One recent example is the discovery of epigenetic antagonism between the polycomb family member EZH2 and SWI/SNF complexes in malignant rhabdoid tumors. Polycomb group proteins contribute to epigenetic-driven gene silencing during development, and increasing evidence supports a critical role for this protein class in oncogenesis. EZH2 is the core catalytic protein in the polycomb repressor complex 2 (PRC2) and catalyzes the trimethylation of histone 3 lysine 27 (H3K27), leading to the repression of hundreds of genes in embryonic stem cells.[437] EZH2 forms a complex with other PRC2 components, including the cofactors SUZ12 and EED and the protein Jarid2, which recruit PRC2 to promoters. EZH2 has been implicated in numerous malignancies. It is highly expressed in many tumors, including those of the breast, prostate, colon, and pancreas, as well as lymphomas and sarcomas.[438] In 2010 the discovery was made of recurrent Tyr 641 mutations in the catalytic SET domain of *EZH2* in diffuse large

B-cell lymphomas and in follicular lymphomas, which increase H3K27me3 in an interaction with the remaining wild-type *EZH2* allele.[439-441] More recently, a tumor-suppressor function of EZH2 in some malignancies has been described. Homozygous deletions or inactivating mutations have been reported in approximately 6% of myelodysplastic syndrome and in certain subsets of myeloproliferative disease.[442-445] Moreover, loss of *EZH2* is reported to cause aggressive T-ALL in mice, and loss-of-function mutations in multiple members of the PRC2 complex, including *EZH2*, *SUZ12*, and *EED*, have been reported in adult and early precursor T-ALL.[257,446,447]

Recent studies support the role for EZH2 dependency in malignant rhabdoid tumor. The first line of evidence that SWI/SNF complexes oppose epigenetic silencing by polycomb group proteins was supported by genetic studies in *Drosophila* species in which defects in body segment identity induced by mutations in polycomb proteins were suppressed by mutations in the SWI/SNF complex.[448] It was later discovered that polycomb proteins can oppose the enzymatic activity of the SWI/SNF complex.[449,450] Malignant rhabdoid tumors, a highly aggressive pediatric malignancy, arise from the biallelic inactivation of *SNF5*, a SWI/SNF complex member.[451,452] It was reported that EZH2 expression and H3K27me3 levels at lineage-specific target genes are upregulated in these SNF5-deficient tumors, with SNF5 directly repressing EZH2 expression.[453] Reduction of EZH2 levels in primary cells lacking SNF5 expression led to downregulation of stem cell signatures. Moreover, it was determined that EZH2 is required for the development and growth of tumor cells with biallelic inactivation of *SNF5*. Although these studies were performed with genetic manipulation, it has only recently become possible to selectively inhibit the enzymatic activity of EZH2 with a small molecule inhibitor with the development of EZH2 inhibitors by multiple pharmaceutical companies.

Small molecule inhibitors of EZH2 were initially described and reported in *EZH2*-mutated lymphoma, in which as many as 22% of germinal center diffuse large B-cell lymphoma and follicular lymphomas harbor mutations in the Y641, located in the catalytic SET domain of *EZH2*. GSK126, a selective S-adenosyl-methionine competitive small molecule inhibitor of EZH2 methyltransferase activity, was reported to decrease global H3K27me3 levels, activate the expression of genes suppressed by PRC2, and inhibit *EZH2*-mutated lymphoma in vitro and in xenograft mouse models of the disease.[454] Similarly, the compound EPZ005687 was reported to reduce H3K27 methylation in lymphoma cells, resulting in apoptosis of lymphoma cells with heterozygous mutations in Y671 or A677, but with little effect on lymphoma cells with wild-type EZH2.[455] A second-generation EZH2 inhibitor, EPZ-6438, with improved potency and pharmacokinetics from EPZ005687, was developed and tested in malignant rhaboid tumor.[456] This compound had remarkable activity, with treatment leading to a dose-dependent regression of malignant rhabdoid tumors in mouse models of disease, a decrease in intratumoral levels of H3K27me3, and even prevention of regrowth after treatment was discontinued. This study demonstrated the dependency of rhabdoid tumors on not only the EZH2 protein but specifically the enzymatic activity of this molecule.

EZH2 has been implicated in other pediatric malignancies. For example, in Ewing sarcoma EWS-FLI has been reported to directly upregulate the expression of EZH2.[457,458] In this study EZH2 was reported to regulate the expression of genes related to stemness and to genes involved in neuroectodermal and endothelial differentiation. Furthermore, in this study the downregulation of EZH2 by shRNA suppressed oncogenic transformation in Ewing sarcoma cells by inhibiting in vitro clonogenicity. Whether Ewing cells depend on the enzymatic activity of EZH2 or another function of the EZH2 protein (as has been implicated in prostate cancer)[459] has yet to be determined. Finally, a potential role for EZH2 has been implicated in neuroblastoma. Here, EZH2 has been found to be physically associated with MYCN in a complex and shRNA directed against EZH2 to alter growth of neuroblastoma cells.[460,461] However, as in Ewing sarcoma, the therapeutic role of EZH2 inhibition in neuroblastoma has not been fully explored. As in the examples discussed previously for other epigenetic modifying drugs, EZH2 inhibitors are now entering clinical trials for adults with cancer.

DOT1L in Mixed-Lineage Leukemia-Rearranged Leukemia

As discussed before, epigenetic modifiers have come to the forefront as therapeutic targets in multiple pediatric cancers. Mixed-lineage leukemia (MLL)-rearranged leukemia represents another illustrative example of a defined genetic subtype of childhood leukemia in which multiple epigenetic vulnerabilities have been identified.[462,463] There are two primary genetic aberrations of *MLL* in leukemia. The most common event is a balanced translocation; more than 70 different fusion partners with *MLL* have been described. A second class of aberration of the *MLL* gene creates a repeat within the N-terminal of MLL resulting in an internal partial tandem duplication (PTD). As noted above, BRD4 has emerged as one potential target in this genetic subtype of leukemia. Another potential target is the H3K79 methyltransferase DOT1L (Fig. 44-8). Whereas MLL-fusion proteins have lost the histone H3K4 methyltransferase activity of wild-type MLL, many of these fusion proteins have been shown to copurify with protein complexes normally involved in transcriptional elongation and activation, such as polymerase-associated factor complex (PAFc), P-TEFb, and DOT1L.[464] It has thus been hypothesized that MLL-fusion proteins promote leukemia through enhanced elongation or activation of leukemia-promoting genes.

The association of MLL fusions with DOT1L precipitated the study of H3K79 methylation levels in *MLL*-rearranged leukemia. Numerous studies demonstrate enhanced H3K79 methylation associated with genes overexpressed in *MLL*-rearranged leukemia cells.[465-467] As in the studies of EZH2 and malignant rhaboid tumor, a therapeutic effect of targeting DOT1L in the context of certain MLL fusions has been demonstrated with both genetic and chemical approaches. In one study abnormal H3K79me2 profiles were identified on MLL-AF9 fusion

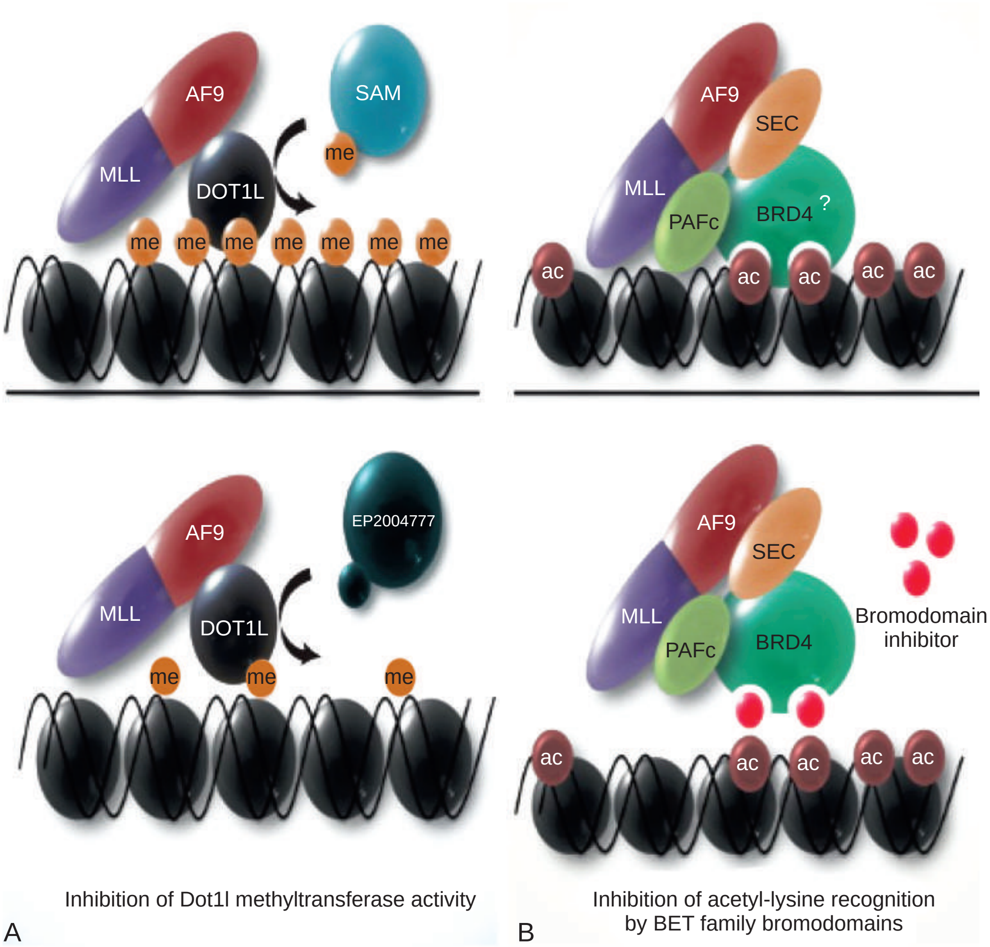

Figure 44-8 Pharmacologic targeting of chromatin regulator pathways in mixed-lineage leukemia (MLL)-rearranged leukemias. **A,** Depiction of the association of DOT1L with the AF9 component of the MLL-AF9 fusion. DOT1L methylates histone 3 at lysine residue 79 by using S-(5′-adenosyl)-1-methionine (SAM) as a donor. The use of a SAM mimetic (e.g., EPZ004777), as shown in the lower panel, can potentially inhibit DOT1L activity and target oncogenic H3K79 hypermethylation. **B,** MLL fusions recruit polymerase-associated factor complex (PAFc) through the N-terminal portion of MLL. A number of nuclear fusion partners, such as AF9 and ENL, are members of the super elongation complex (SEC), which includes positive transcription elongation factor b (P-TEFB). Both PAFc and P-TEFb have been implicated in MLL-fusion positive leukemias. The BET family member BRD4 was shown to co-purify with several components of the PAFc and SEC. Small molecule inhibitors of BRD4, which inhibit its recognition of acetyl lysine, impair the targeting of the PAFc and SEC components to chromatin, leading to altered gene expression. BRD4 inhibitors might therefore inhibit MLL-mediated leukemogenesis. *(Modified from Deshpande, et al: Chromatin modifications as therapeutic targets in MLL-rearranged leukemia.* Trends Immunol *33:563–570, 2012.)*

target loci in leukemic stem cells and inactivation of Dot1l led to the downregulation of MLL-AF9 target genes.[468] Moreover, in this study, by using an experimentally derived mouse model of MLL-AF9 leukemia, it was determined that Dot1l is required in vivo for both leukemic transformation and maintenance. Similar findings were observed in an independent study by using a tamoxifen-inducible Cre-mediated loss-of-function mouse model in which it was demonstrated that Dot1l is required for the initiation and maintenance of MLL-AF9–induced leukemogenesis in vitro and in vivo.[469] The critical relevance of the enzymatic activity of DOT1L in *MLL*-rearranged leukemia was determined with the testing of EPZ004777, a selective small molecule inhibitor of DOT1L. Treatment of MLL cells with the compound inhibited H3K79 methylation, blocked expression of leukemogenic genes, resulted in the selective killing of *MLL*-rearranged leukemia cells, and led to a modest extension of survival in a mouse MLL-leukemia xenograft model.[470] Subsequently, it was demonstrated that other MLL fusions, including MLL-AF6, MLL-AF10, and CALM-AF10, require the H3K79 methyltranasferase activity of DOT1L.[471,472] As in the case of BET bromodomain and EZH2 inhibitors, DOT1L inhibitors are just beginning to enter clinical trials.

CONCLUSIONS

Tremendous progress has been made in the treatment of pediatric cancer over the last century. The empiric combination of cytotoxic agents has proved curative for many patients, but at the expense of toxicity. Over the last decade, heralded by the success of targeting BCR-ABL in CML, we have entered a new era of drug discovery with an emphasis on target-based treatment with the promise of improved cure rates and decreased toxicity. New and developing high-throughput genomic and proteomic technologies are dramatically altering the landscape of research, enabling the identification and credentialing of new targets with a speed previously unfathomable. In this chapter we have provided a framework for classifying and credentialing new targets. We have highlighted examples of successful targeted approaches from the treatment of adults with cancer and have discussed emerging targets for pediatric cancer. Although it is an exciting time in cancer therapy, there are many sobering challenges that lie ahead in the development of targeted therapy, particularly for pediatric cancer. Continued advancement will require innovative approaches to intractable targets (e.g., transcription factors), rational approaches to combination therapy, and collaborative efforts between industry and academic centers to identify new pediatric targets along with target-specific drugs. For maximal progress in the treatment of children with cancer, we will need to collectively solve the issues that confront the clinical development of novel therapeutics. Trials that allow for biopsies, genetic profiling of tumors, and "window" treatment periods may be necessary to bring targeted therapies into the pediatric realm.

CHAPTER 45

Cytogenetic and Molecular Pathology of Pediatric Cancer

Maureen J. O'Sullivan, Carolyn A. Felix, and **Jonathan A. Fletcher**

CHAPTER OUTLINE

CYTOGENETIC AND MOLECULAR METHODOLOGIES
- Karyotyping
- Molecular Cytogenetics
- Polymerase Chain Reaction–Based Molecular Assays
- Array Comparative Genomic Hybridization and Single Nucleotide Polymorphism Profiling Assays
- Next-Generation Sequencing and Other Techniques

GENOMIC MECHANISMS IN PEDIATRIC TUMORS
- Causes and Predisposing Factors for Chromosomal Translocations

BIOLOGIC CONSEQUENCES OF CHROMOSOMAL TRANSLOCATION
- Chromosomal Rearrangements Involving Transcription Factor Genes
- Chromosomal Rearrangements Involving Protein Tyrosine Kinase Genes
- Chromosomal Rearrangements Associated with Transcriptional Upregulation of Nonfusion Oncogenes

BIOLOGIC BASIS FOR SPECIFICITY OF BALANCED CHROMOSOMAL REARRANGEMENTS: DIAGNOSTIC RELEVANCE

CYTOGENETIC AND MOLECULAR PATHOLOGY: MAJOR TUMOR TYPES
- Mesenchymal Neoplasms: Soft Tissue and Bone Tumors
- Nonmesenchymal Solid Tumors
- Blastomas
- Central Nervous System Tumors
- Germ Cell Tumors
- Hematologic Neoplasms

Cytogenetic and molecular analyses have provided pivotal biologic and clinical insights into pediatric neoplasia. It is increasingly evident that genetic assays of various types can provide essential diagnostic or prognostic information about pediatric solid tumors and hematologic malignancies (Tables 45-1 to 45-3). In this chapter we offer an overview of the methods in use for the analysis of cytogenetic and molecular aberrations (Table 45-4) in pediatric cancers together with their relative attributes, discuss the causes of these genetic aberrations, and summarize their diagnostic and predictive relevance in clinical practice.

CYTOGENETIC AND MOLECULAR METHODOLOGIES

The pathognomonic genetic aberrations in pediatric cancer can be evaluated by various methods. Because each of these methods has a different profile of substrate requirements, sensitivity, and specificity (see Table 45-4), the optimal approach must be tailored individually in regard to both the nature and quantity of material available and to the precise information being sought.

Karyotyping

The traditional karyotype provides a low-resolution snapshot of the entire genome. Cells are cultured, arrested in metaphase, and then subjected to staining of the chromosomes to produce characteristic banding patterns,[1-4] which are described using standardized nomenclature (Box 45-1). Probably the major advantage of karyotypic analysis is the provision of a global overview of the chromosomal composition of a cultured cellular population without any requirement for preknowledge, especially enabling the identification of completely novel aberrations (Fig. 45-1). However, karyotyping has distinct limitations, including the requirement for fresh material in sufficient amounts and slow turnaround because of time required for tumor cell growth.

Need for Sufficient Viable Tumor Cells

Solid tumors may comprise substantial nonviable or hypocellular regions containing few neoplastic cells. Such regions may be extensively necrotic because the tumor cells have died, having outstripped their blood supply.

Text continued on p. 1345

TABLE 45-1 Typical Genetic Aberrations in Soft Tissue and Bone Tumors

Histologic Findings	Cytogenetic Events	Molecular Events	Frequency (%)	Clinical Relevance
Alveolar soft part sarcoma	t(X;17)(p11;q25)	*ASPSCR1 (ASPL)-TFE3* fusion	>90	
Aneurysmal bone cyst (extraosseous)	16q22 and 17p13 rearrangements	*USP6* fusion genes	>50	
Angiomatoid fibrous histiocytoma	t(12;16)(q13;p11)	*FUS-ATF1* fusion	10	
		EWSR1 (EWS)-GREB1 fusion	80	
Chondromyxoid fibroma	Deletion of 6q		>75	
Chondrosarcoma				
Skeletal	Complex*		>75	
Extraskeletal myxoid	t(9;22)(q22;q12)	*EWS-NR4A3* fusion	>75	
	t(9;17)(q22;q11)	*TAF15-NR4A3* fusion	<10	
	t(9;15)(q22;q21)	*TCF12-NR4A3* fusion	<10	
Clear cell sarcoma—melanoma of soft parts	t(12;22)(q13;q12)	*EWS-ATF1* fusion	>	
Dermatofibrosarcoma protuberans	Ring form of chromosomes 17 and 22	*COL1A1-PDGFB* fusion	>75	PDGFRB therapeutic inhibition
	t(17;22)(q21;q13)	*COL1A1-PDGFB* fusion	10	PDGFRB therapeutic inhibition
Desmoplastic small round cell tumor	t(11;22)(p13;q12)	*EWS-WT1* fusion	>75	
Endometrial stromal tumor	t(7;17)(p15;q21)	*JAZF1-SUZ12*	30	
Ewing sarcoma	t(11;22)(q24;q12)	*EWS-FLI1* fusion	>80	
	t(21;22)(q12;q12)	*EWS-ERG* fusion	5-10	
	t(2;22)(q33;q12)	*EWS-FEV* fusion	<5	
	t(7;22)(p22;q12)	*EWS-ETV1* fusion	<5	
	t(17;22)(q12;q12)	*EWS-ETV4* fusion	<5	
	t(16;21)(p11;q12)	*FUS-ERG* fusion	<5	
	t(2;16)(q33;p11)	*FUS-FEV* fusion	<5	
	inv(22)(q12q12)	*EWS-PATZ1 (ZSG)* fusion	<5	
Fibromatosis (desmoid)	Trisomies 8 and 20		30	
	Deletion of 5q	*APC* inactivation	10	Association with germline *APC* mutation and familial adenomatous polyposis
		CTNNB1 mutation	70	
Fibromyxoid sarcoma, low-grade	t(7;16)(q33;p11)	*FUS-CREB3L2 (BBF2H7)* fusion	50	
Fibrosarcoma, infantile	t(12;15)(p13;q26)	*ETV6 (TEL)-NTRK3* fusion	>75	NTRK3 therapeutic inhibition
	Trisomies 8, 11, 17, and 20		>75	
Gastrointestinal stromal tumor	Monosomies 14 and 22		>75	
	Deletion of 1p		>25	
		KIT or *PDGFRA* mutation	>90	KIT-PDGFRA therapeutic inhibition
Giant cell tumor				
Bone	Telomeric associations		>50	
Tenosynovial	Trisomies 5 and 7		>25	
	t(1;2)(p13;q35)	*CSF1-COL6A3* fusion	25	CSF1R therapeutic inhibition
Hibernoma	11q13 rearrangement		>50	

TABLE 45-1 Typical Genetic Aberrations in Soft Tissue and Bone Tumors (Continued)

Histologic Findings	Cytogenetic Events	Molecular Events	Frequency (%)	Clinical Relevance
Inflammatory myofibroblastic tumor	2p23 rearrangement	*ALK* fusion genes	50	ALK therapeutic inhibition
Leiomyoma				
Uterine	t(12;14)(q15;q24) or deletion of 7q	*LHFP (HMGIC)* rearrangement	40	
Extrauterine	Deletion of 1p		?	
Leiomyosarcoma	Deletion of 1p		>50	
Lipoblastoma	8q12 rearrangement or polysomy 8	*PLAG1* oncogenes	>80	
Lipoma				
Typical	12q15 rearrangement	*HMGIC* rearrangement	60	
Spindle cell or pleomorphic	Deletion of 13q or 16q		>75	
Chondroid	t(11;16)(q13;p12-13)		?	
Liposarcoma				
Well-differentiated	Ring form of chromosome 12		>75	
Myxoid, round cell	t(12;16)(q13;p11)	*FUS-DDIT3 (CHOP)* fusion	>75	Trabectedin therapeutic response
	t(12;22)(q13;q12)	*EWS-CHOP* fusion	<5	
Pleomorphic	Complex*		90	
Malignant fibrous histiocytoma				
Myxoid	Ring form of chromosome 12		?	
High-grade	Complex*		>90	
Myxofibrosarcoma	(see "Malignant fibrous histiocytoma")			
Malignant peripheral nerve sheath tumor	(see "Schwannoma")			
Mesothelioma	Deletion of 1p	*?BCL10* inactivation	>50	
	Deletion of 9p	*p15*, *p16*, and *p19* inactivation	>75	
	Deletion of 22q	*NF2* inactivation	>50	
	Deletions of 3p and 6q		>50	
Neuroblastoma				
Good prognosis	Hyperdiploid, no 1p deletion		40	
Poor prognosis	1p deletion		40	
	Double-minute chromosomes	*MYCN* amplification	>25	
Oligodendroglioma	Deletion of 1p and 19q			Therapeutic response to CDDP
Osteochondroma	Deletion of 8q	*EXT1* inactivation	>25	
Osteosarcoma				
Low-grade	Ring chromosomes		>50	
High-grade	Complex*	*RB1* and *TP53* inactivation	>80	
Pericytoma	t(7;12)(p22;q13-15)	*GLI-ACTB* fusion	?	
Pigmented villonodular synovitis	(see "Giant cell tumor: Tenosynovial")			
Primitive neuroectodermal tumor	(see "Ewing sarcoma")			
Rhabdoid tumor	Deletion of 22q	*SMARCB1 (INI1)* inactivation	>90	

Continued on following page

TABLE 45-1 Typical Genetic Aberrations in Soft Tissue and Bone Tumors (Continued)

Histologic Findings	Cytogenetic Events	Molecular Events	Frequency (%)	Clinical Relevance
Rhabdomyosarcoma				
Alveolar	t(2;13)(q35;q14)	*PAX3-FOXO1* fusion	60	Prognosis
	t(1;13)(p36;q14), double minutes	*PAX7-FOXO1* fusion	10-20	Prognosis
Embryonal	Trisomies 2q, 8 and 20		>75	
		Loss of heterozygosity at 11p15	>75	
Schwannoma				
Benign	Deletion of 22q	*NF2* inactivation	>80	
Malignant, low-grade	None			
Malignant, high-grade	Complex*		>90	
Synovial sarcoma				
Monophasic	t(X;18)(p11;q11)	*SS18 (SYT)-SSX1* or *SYT-SSX2* fusion	>90	Prognosis
Biphasic	t(X;18)(p11;q11)	*SYT-SSX1* fusion	>90	
Wilms tumor	Deletion 11p13	*WT1* inactivation		Association with syndromic Wilms tumor
	1p deletion			Adverse prognosis in low-stage FH
	16q deletion			Adverse prognosis in low-stage FH
	1q gain			Increased relapse risk

CDDP, *cis*-Diamminedichloroplatinum; *FH*, favorable histology; *PDGFRA*, platelet-derived growth factor receptor alpha; *PDGFRB*, platelet-derived growth factor receptor beta.

*Indicates presence of complicated numeric and structural chromosomal aberrations.

TABLE 45-2 Typical Genetic Aberrations in Pediatric Lymphomas

Histologic Findings	Cytogenetic Events	Molecular Events	Frequency (%)
Hodgkin, classic	Complex*	Clonal Ig rearrangements	95
		Clonal *IGH* translocations	17
		Clonal *IGK* translocations	1
		Clonal *IGL* translocations	3
		Clonal TCR rearrangements	1-2
Hodgkin, nodular lymphocyte predominance	t(3;14)(q27;q32)	*BCL6* rearrangement	50
Burkitt	t(8;14)(q24;q32)	*IGH-MYC* rearrangement	80
	t(2;8)(p11;q24)	*IGK-MYC* rearrangement	5
	t(8;22)(q24;q11)	*IGL-MYC* rearrangement	15
Lymphoblastic (see Table 45-4) ALL

TABLE 45-3 Typical Genetic Aberrations in Pediatric Leukemias and Myeloproliferative Disorders (Continued)

Histologic Findings	Cytogenetic Events	Molecular Events	Frequency	Clinical Relevance
Precursor B-cell ALL	Chromosome band 11q23 translocations	*MLL (KMT2A)* gene rearrangements	80% of infant ALL	Poor prognosis especially in ALL and therapy-related cases, associated with FAB M4, FAB M5, other AML morphologies, leukemia cutis, extramedullary involvement, and topoisomerase II (TOP2) poison exposure
	Hyperdiploidy		30% precursor B-cell ALL	Favorable prognosis if >50 chromosomes and specific trisomies
	Hypodiploidy		6%-8% precursor B-cell ALL	Unfavorable prognosis if <44 chromosomes, −7, dicentric chromosome
	t(12;21)(p13;q21) (cryptic; detectable by FISH only)	*TEL-AML1* fusion	25% of “common” ALL	Favorable prognosis
	t(9;22)(q34;q11)	*BCR-ABL1* fusion	5% precursor B-cell ALL	Poor prognosis, associated with older age, imatinib mesylate sensitivity
	t(1;19)(q23;p13.3)	*E2A-PBX1* fusion	~4% Precursor B-cell ALL; 25% cIg+ cases; <1% cIg– cases	Poor prognosis in cIg+ cases
	t(17;19)(q22;p13.3)	*E2A-HLF* fusion	1% precursor B-cell ALL	Coagulopathy, poor prognosis
	t(5;14)(q31;q32)	*IGH-IL3* fusion	<1% precursor B-cell ALL	Peripheral eosinophilia
	t(6;14)(p22.3;q32)	*IGH-ID4* fusion	?	Favorable prognosis
	t(1;19)(q23;p13.3)	*MEF2D-DAZAP1* fusion	?	
		FLT3 point mutation	5% childhood precursor B-cell ALL, 16% infant ALL, ~21%-28% high hyperdiploid ALL, 18% *MLL*-rearranged ALL	Poor prognosis, increased FLT3-ITD allelic ratio associated with AML relapse, sensitivity to FLT3 tyrosine kinase inhibition
		*FLT3*ITD	2% precursor B-cell ALL	Poor prognosis, increased FLT3-ITD allelic ratio associated with AML relapse, sensitivity to FLT3 tyrosine kinase inhibition
		IKZF1 mutations	10%-15% of precursor B-cell ALL	Poor prognosis
	iAMP21	Accompanying *IKZF1, CDKN2A/B, PAX5, ETV6,* and *RB1* alterations	~2% of B-cell precursor ALL in older children	Poor outcome with standard regimens
Precursor B-cell ALL,	Chromosome band 9p21 deletion	*CDKN2A (p16*^{INK4A}-*p14*^{ARF} deletion; variable *CDKN2B* (*p15*^{INK4B}) deletion		Associated with relapse, poor prognosis
Precursor B-cell ALL “Ph-like ALL”	Cryptic rearrangements *EBF1-PDGFRB, BCR-JAK2, STRN3-JAK2, PAX5-JAK2, NUP214-ABL1, ETV6-ABL1, RANBP2-ABL1, RCSD1-ABL1, IGH-EPOR* *SH2B3* deletion	May also have *IL7R* mutation. Accompanying *IKZF1* deletions (40%) Accompanying *JAK* mutations	10% of precursor B-cell ALL, ~15% of cases of high-risk precursor B-cell ALL	Poor prognosis, preclinically responsive to TKI and JAK inhibition

TABLE 45-3 Typical Genetic Aberrations in Pediatric Leukemias and Myeloproliferative Disorders (Continued)

Histologic Findings	Cytogenetic Events	Molecular Events	Frequency	Clinical Relevance
Precursor B-cell ALL and precursor B-cell ALL in DS	*CRLF2* rearrangements (Xp22.3/Yp11.3) with IGH (14q32) *CRLF2* interstitial deletion (*P2RY8-CRLF2* rearrangement)	*CFLF2* lesion may be F232C point mutation Accompanying *JAK1* or *JAK2* mutations in 50% Accompanying *IKZF1* mutation/deletion Accompanying *IL7R*	Ph-like ALL, 15% of high-risk precursor B-cell ALL, 60% Down syndrome ALL, in non-DS high-risk ALL	Associated with poor prognosis high relapse rate, high MRD, associated with Hispanic ethnicity; preclinically responsive to signal transduction inhibitors (JAK, PI3K/mTOR)
B-cell ALL	t(8;14)(q24;q32)	*IGH-MYC* fusion	Rare	Poor prognosis
	t(2;8)(p12;q24)	*IGK-MYC* fusion	Rare	
	t(8;22)(q24;q11)	*IGL-MYC* fusion	Rare	
AML	t(8;21)(q22;q22)	*AML1-ETO* fusion	~12% pediatric AML	Associated with FAB M2 morphology, granulocytic sarcoma presentation, favorable prognosis
	Chromosome band 11q23 translocations	*MLL* gene rearrangements	80% myelomonocytic-monoblastic AML in infants and young children; ~7%-18% pediatric AML	Poor prognosis especially in ALL and therapy-related cases, associated with FAB M4, FAB M5, other AML morphologies, leukemia cutis, extramedullary involvement, TOP2 poison exposure
	inv(16)(p13q22) or t(16;16)(p13;q22)	*CBF-MYH11* fusion	~7% pediatric AML	Associated with abnormal eosinophils (adults), FAB M2 or M4 AML without eosinophilia (pediatrics), favorable prognosis
	t(8;16)(p11;p13)	*MOZ-CBP* fusion	Rare	Unfavorable prognosis, erythrophagocytosis, coagulopathy, associated with leukemia cutis and spontaneous remission in neonates
	t(6;9)(p23;q34)	*DEK-NUP214 (CAN)* fusion	Rare	Unfavorable prognosis
	May be associated with t(8;21) or inv(16)	*KIT* mutation	37% CBF AML	Sensitivity to imatinib, sensitivity to FLT3 tyrosine kinase inhibition
		NPM mutation	~7%-8% pediatric AML	Favorable prognosis in absence of *FLT3* ITD
		FLT3 point mutation	7%-9% pediatric AML	Poor prognosis, increased FLT3-ITD allelic ratio associated with AML relapse, sensitivity to FLT3 tyrosine kinase inhibition
		FLT3-ITD	~12%-15% pediatric AML	Poor prognosis, increased FLT3-ITD allelic ratio associated with AML relapse, sensitivity to FLT3 tyrosine kinase inhibition
APL	t(11;17)(q23;q21)	*PLZF-RARA* fusion	Rare	Insensitive to ATRA
		FLT3-ITD	~30% pediatric APL	
Therapy-related APL	t(15;17)(q22;q21)	*PML-RARA* fusion		Favorable prognosis, ATRA sensitivity, arsenic trioxide sensitivity
Therapy-related MDS/AML, de novo MDS/AML	Monosomy 7/del(7q)		~40% pediatric MDS, 49% RC, 4%-5% pediatric AML	Alkylating agent exposure, associated with disease progression, poor prognosis, can be familial
De novo or therapy-related AML, ALL, MDS	Chromosome band 11p15 translocations	*NUP98* gene rearrangements	?	

Continued on following page

TABLE 45-3 Typical Genetic Aberrations in Pediatric Leukemias and Myeloproliferative Disorders (Continued)

Histologic Findings	Cytogenetic Events	Molecular Events	Frequency	Clinical Relevance
Therapy-related MDS/AML	Monosomy 5, del(5q)			Alkylating agent exposure
	May be associated with segmental jumping translocations	*TP53* mutation	? (more common in therapy-related than de novo MDS, AML)	Alkylating agent exposure, associated with AML in Li-Fraumeni syndrome
Therapy related ALL and AML after exposure to TOP2 poisons	Chromosome band 11q23 translocations	*MLL* gene rearrangements		Poor prognosis especially in ALL and therapy-related cases, associated with FAB M4, FAB M5, other AML morphologies, leukemia cutis, extramedullary involvement, TOP2 poison exposure
5q– syndrome, refractory anemia	del(5q)	*RPS14* deletion	?—not described in children	Lenalidomide sensitivity
JMML, AML, MDS, precursor B-cell ALL		*PTPN11* mutation	30%-35% of JMML, 4% of AML, 18% of FAB M5 AML	Associated with Noonan syndrome
JMML	May be associated with monosomy 7	*NF1* mutation	~30% of JMML, ~50% of JMML in constitutional NF1 syndrome	Associated with constitutional NF1 syndrome
JMML, AML, MDS	May be associated with monosomy 7 in JMML/MDS or with t(8;21) or inv(16) in AML	*KRAS* or *NRAS* mutation	20%-30% JMML, ~20%-30% pediatric AML, 30% monosomy 7 MDS	
CMML	t(5;12)(q33;p13)	*TEL-PDGFRB* fusion	Rare	Associated with eosinophilia, progression to AML
TAM, AMKL	May be associated with +8 if progression to AMKL	*GATA1* mutations		Associated with Down syndrome
Non–Down syndrome AMKL	t(1;22)(p13;q13)	*OTT-MAL* fusion	Rare	Found in neonates
Refractory cytopenia (RC)	Trisomy 8		9% of RC	

ALL, Acute lymphocytic leukemia; *AMKL,* acute megakaryoblastic leukemia; *AML,* acute myeloid leukemia; *APL,* acute promyelocytic leukemia; *CBF,* core-binding factor; *CMML,* chronic myelomonocytic leukemia; *FAB,* French-American-British classification; *FISH,* fluorescence in situ hybridization; *ITD,* internal tandem duplication; *JMML,* juvenile myelomonocytic leukemia; *MDS,* myelodysplastic syndrome; *MRD,* minimal residual disease; *NF1,* neurofibromatosis type 1; *TAM,* transient abnormal myelopoiesis.

TABLE 45-4 Complementary Nature of Cytogenetic and Molecular Assays

	METHOD				
Assay Consideration	Karyotyping	FISH	CGH	SNP	PCR Sequencing
Cost of assay	High	Low	High	High	Low
What types of tumor material can be used?	Fresh	Any	Fresh, frozen*	Fresh, frozen*	Any
Does assay detect translocations?	Yes	Yes	No	No	Yes
Does assay detect point mutations?	No	No	No	No	Yes
Does assay detect deletions?	Yes	Yes	Yes	Yes	Yes, if qPCR
Does assay detect amplifications?	Yes	Yes	Yes	Yes	Yes, if qPCR
Does assay detect low-frequency mutations?	No	Yes; 1 in 100	No	No	Yes; 1 in 10,000
Does assay permit genome-wide evaluation?	Yes	No	Yes	Yes	No

CGH, Comparative genomic hybridization; *FISH,* fluorescence in situ hybridization; *PCR,* polymerase chain reaction; *qPCR,* quantitative PCR; *SNP,* single-nucleotide polymorphism analysis.

*Can be performed using DNA extracted from paraffin materials, but with some loss of resolution.

Other regions of a tumor mass may be composed largely of blood (hemorrhage) or scar tissue (fibrosis). Therefore in the case of solid tumor karyotyping, it is crucial that the pathologist select a maximally viable region for analysis.

Unpredictable Tumor Cell Growth in Culture

Even when tumor tissue has been selected from an optimal region, the unpredictable growth of neoplastic cells in culture remains a major consideration. Benign tumors often contain only few mitotic cells and so one generally has to wait several days before such specimens proliferate actively in culture. In the meantime, the culture may become overgrown by nonneoplastic cells, such as fibroblasts. Perhaps surprisingly, even highly malignant solid tumors may grow poorly in tissue culture, despite the fact that they grew well in the patient. Such tumor cultures may occasionally be stimulated by the use of specialized culture media or growth factors,[5] but it is impractical in most clinical cytogenetic laboratories to troubleshoot tissue cultures to optimize the growth of each tumor type. Therefore in practice it may be challenging to culture and

Box 45-1 **Cytogenetic Abbreviations and Definitions**

cDNA: complementary DNA
cen: centromere
CGH: comparative genomic hybridization
CISH: chromogenic in situ hybridization
del: deletion
dmin; double minute chromosome (extrachromosomal amplicon)
FISH: fluorescence in situ hybridization
hsr: homogeneously staining region (intrachromosomal amplicon)
ins: insertion within chromosome
inv: inversion of chromosome segment
ISH: in situ hybridization
mar: marker chromosome (aberrant chromosome whose origin cannot be ascertained)
p: chromosome short arm
q: chromosome long arm
r: ring chromosome
SKY: spectral karyotyping
t: translocation
tel: telomere

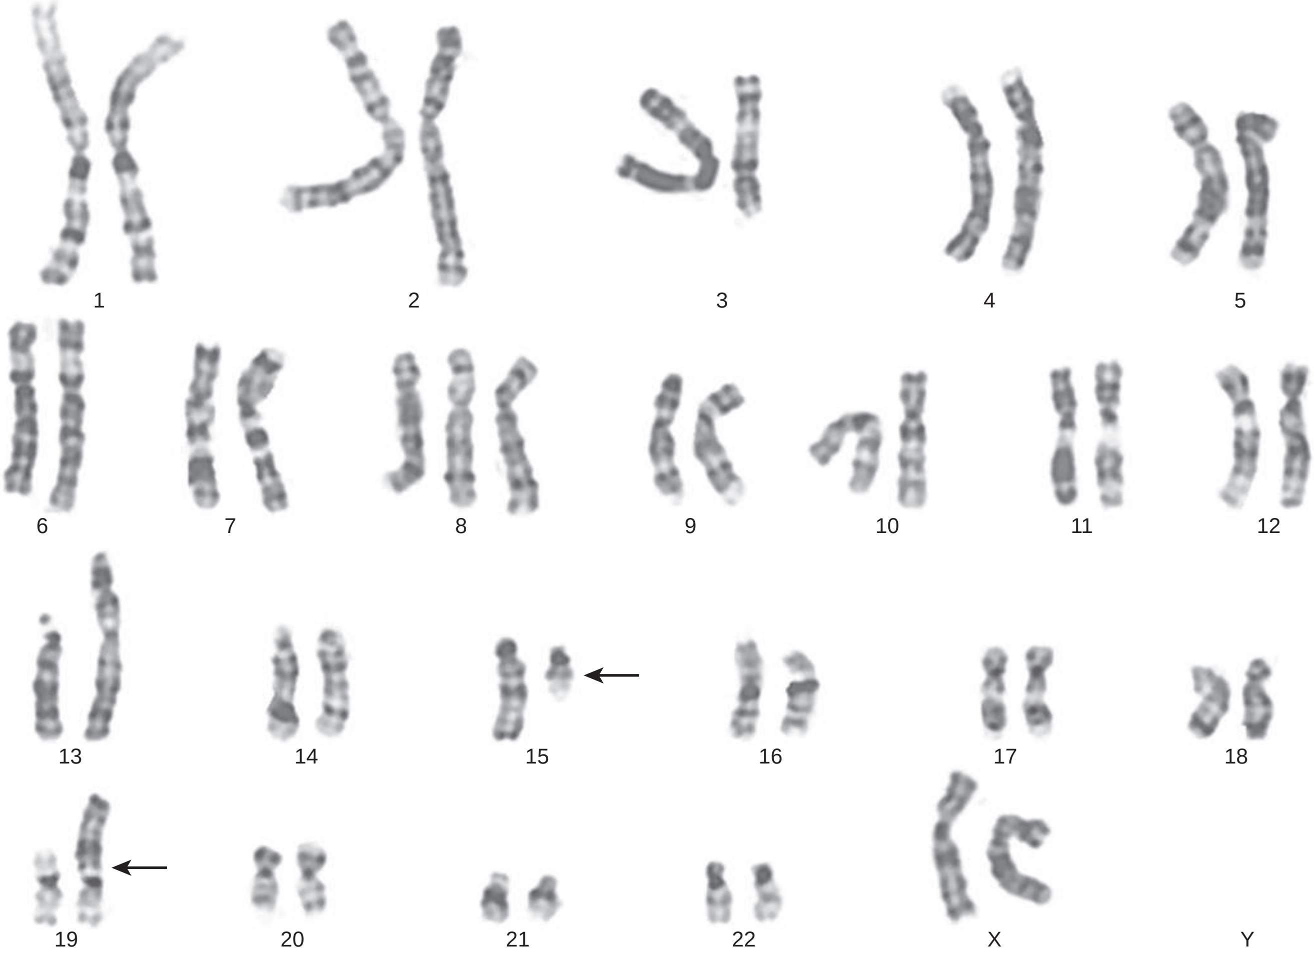

Figure 45-1 Giemsa-banded karyotype of highly lethal NUT midline carcinoma, demonstrating balanced t(15;19) with *arrows* indicating the translocation breakpoints. Other cytogenetic findings, including chromosome 3 and 13 rearrangements and trisomy 8, are secondary aberrations.

karyotype certain types of pediatric tumors in the clinical laboratory. In the case of bone marrow cytogenetics, it is well known that posttherapeutic specimens can be difficult to analyze, being hypocellular and containing cells—reactive and/or neoplastic—that have been temporarily growth-arrested by therapy and therefore fail to give rise to metaphases in culture.

Nonrepresentative Cell Culture

It is also important to recognize that only a subpopulation of cells within a given sample might be capable of growing under a particular set of culture conditions. Therefore one cannot necessarily assume that a clonally abnormal karyotype is representative of the overall neoplastic process. For example, in a given tumor, the final karyotype might be representative of the components of the tumor that were more or less clinically aggressive, depending on which component was best suited for growth under the particular culture conditions used at that time.

Culture Overgrowth by Nonneoplastic Cells

All tumor samples contain mixtures of neoplastic and nonneoplastic cells. The nonneoplastic elements may include hematopoietic cells, fibroblasts, normal epithelial cells, endothelial cells, or glial cells, depending on the type and location of the tumor. Any of these reactive or support cell types might proliferate more successfully than the neoplastic cells in culture. Invariably, when a pediatric cancer submitted for cytogenetic analysis is reported to have a normal karyotype, the normal karyotype is a false-negative result, only signifying that the culture was overgrown by normal cells. Therefore the cytogenetic analysis must always be timed carefully, so that metaphases are analyzed at a point at which the neoplastic population is actively dividing. This technical challenge can, in the case of solid tumors, be met if the cytogeneticist develops familiarity with the distinctive morphologies of the various neoplastic and reactive cell types and then inspects the tissue cultures daily to determine when the neoplastic cells have the proliferative advantage.[5]

Complex Karyotype

Beyond the initial challenges incurred at the culture stage, various additional considerations influence the success of cytogenetic evaluation in different types of pediatric cancer. For example, conventional karyotyping can be challenging in many high-grade solid tumors, in which the karyotypes are often complex compared with those seen in leukemias and lymphomas. A single metaphase cell from such cancers can contain dozens of clonal and nonclonal chromosomal aberrations, making it impractical to characterize the exact mechanisms of rearrangement responsible for each chromosomal aberration or to estimate the relative significance of any of these abnormalities.

Technical Limitations in Detecting Aberrations

There are certain aberrations that cannot be detected by karyotyping, because the resolution is too low. These include smaller deletions or amplifications and point mutations, but also cryptic or masked aberrations, which include, for example, the chromosomal translocation t(12;15) characteristic of congenital or infantile fibrosarcoma, congenital cellular mesoblastic nephroma, secretory breast carcinomas, and a subset of acute myelogenous leukemias (Fig. 45-2).[6,7] Another translocation that cannot

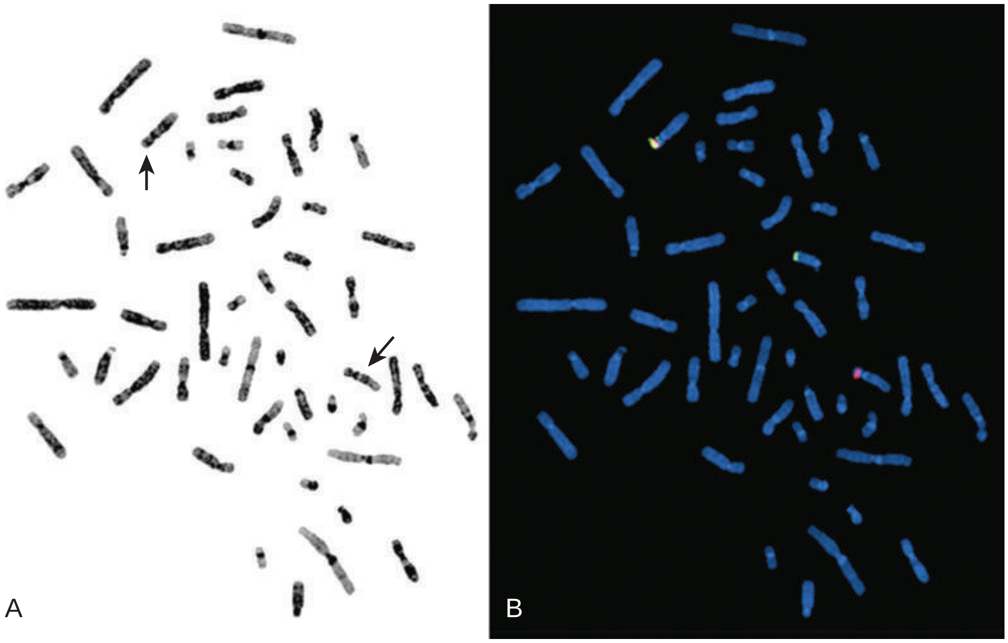

Figure 45-2 **A,** Giemsa banding studies in infantile fibrosarcoma do not reveal the characteristic, but cytogenetically cryptic t(12;15), associated with *TEL-NTRK3* oncogenic fusion. *Black arrows* indicate the normal *(top)* and rearranged *(middle)* copies of chromosome 12, as demonstrated by *TEL* break-apart fluorescence in situ hybridization (FISH). **B,** The FISH studies reveal yellow probe fusion signal on the normal chromosome 12, whereas the t(12;15) results in split red and green FISH signals on rearranged chromosomes 12 and 15, respectively.

be resolved by conventional karyotype analysis is the t(12;21), which is the most common translocation in pediatric leukemia. It is found in a large fraction of common acute lymphoblastic leukemia (ALL) in children and fuses the *ETV6 (TEL)* and *RUNX1 (AML1)* genes.

In essence, then, the major advantage of karyotypic evaluation of solid tumors is the breadth of the data provided. Notable challenges include the successful culture of representative tumor cells, particularly because this is essentially a one-shot approach, with no opportunity to return to the specimen, because the window of opportunity for culture is confined to the short period of viability of fresh cells after biopsy. Even when culture is successful, meaningful interpretation of the findings on karyotype may represent a further challenge, depending on the number and nature of the aberrations.

Although solid tumors are less readily accessible for biopsy compared with hematologic neoplasms, minimally invasive sampling by a percutaneous approach is becoming more common. Needle biopsy is often performed under ultrasound or computed tomographic (CT) guidance and can involve fine-needle aspiration or needle core biopsy of the tumor. Solid tumor samples obtained by these methods can be karyotyped successfully,[8-11] but the small amount of starting material is a constraint in that fewer cultures can be established. Because the successful cytogenetic evaluation of tumors in standard practice is limited by these factors, alternative, more robust methods are needed for the successful routine demonstration of genetic aberrations. Traditionally, these have included fluorescence in situ hybridization (FISH) and polymerase chain reaction (PCR) techniques, which have the distinct advantage of applicability to fixed material and therefore also to large cohorts of archival cases. Both FISH and molecular analyses can be straightforward also in fine-needle specimens.[12,13]

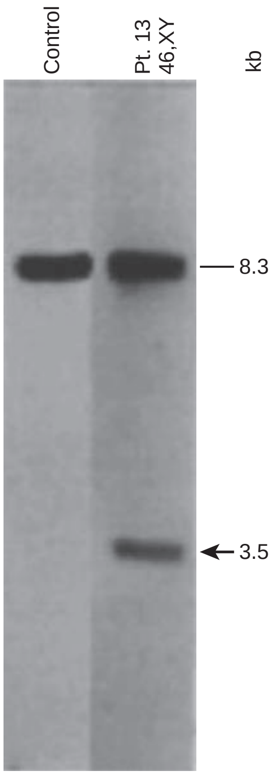

Figure 45-3 Detection of cryptic *MLL* bcr rearrangement by Southern blot analysis in treatment-associated acute myelogenous leukemia (AML). The karyotype was normal, but the French-American-British (FAB) M4 morphology and clinical history of dactinomycin exposure informed further analysis of *MLL*. The *dash* indicates the germline pattern, and the *arrow* shows a rearrangement, which panhandle polymerase chain reaction molecular cloning revealed to be an *MLL* internal tandem duplication. *(Modified from Megonigal MD, Rappaport EF, Jones DH, et al: Panhandle PCR strategy to amplify* MLL *genomic breakpoints in treatment-related leukemias.* Proc Natl Acad Sci U S A *94:11583–11588, 1997.)*

Molecular Cytogenetics

Recombinant DNA Technologies

Southern Blot Analysis. In pediatric solid tumors, leukemias, and lymphomas, recombinant DNA technologies, including Southern blot analyses of candidate genes relevant to particular disease states, can overcome limitations of conventional karyotype analysis for the detection of chromosomal aberrations (Fig. 45-3). Although no longer used extensively in most clinical diagnostic laboratories, Southern blotting has served an important role in gene discovery. That is, genomic Southern blot analyses, coupled with PCR-based molecular cloning and gene sequencing strategies, have identified unknown partner genes fused to various known genes in chromosomal translocations. For example, the demonstration of immunoglobulin *(IG)* and T-cell receptor *(TCR) loci* rearrangements in leukemias and lymphomas, as evidenced by altered size of restriction enzyme fragments on genomic Southern blot analyses, has been essential in highlighting crucial regions that could be studied by molecular cloning strategies and that characterize the genomic translocation breakpoint junction sequences that define these tumors (Fig. 45-4). The molecular principles that provide the basis for current clinical molecular cytogenetic diagnostic strategies (e.g., FISH) in pediatric leukemias and solid tumors are not substantially different from the recombinant DNA concepts used in Southern blotting. Some seminal examples of gene rearrangements characterized originally by Southern blotting and now detected routinely by FISH include *MYC* gene rearrangements, involving the *IGH* or *IGL* chain loci in Burkitt lymphoma,[14] and *MLL (KMT2A)* rearrangements, of which the first characterized type was associated with t(4;11), resulting in *MLL-AFF1 (AF4)* fusion.[15]

Another application of Southern blot analysis has been in discerning gene copy number variation. One example is *MLL* gene amplification (see Fig. 45-4), involving an interlocus DNA rearrangement known as segmental jumping translocation in which the unrearranged *MLL* DNA segment is amplified and translocated to various regions of the genome.[16]

Fluorescence and Chromogenic in Situ Hybridization. Whereas conventional cytogenetic analyses are performed using staining techniques that highlight chromosomal banding patterns (1;2), the various molecular cytogenetic

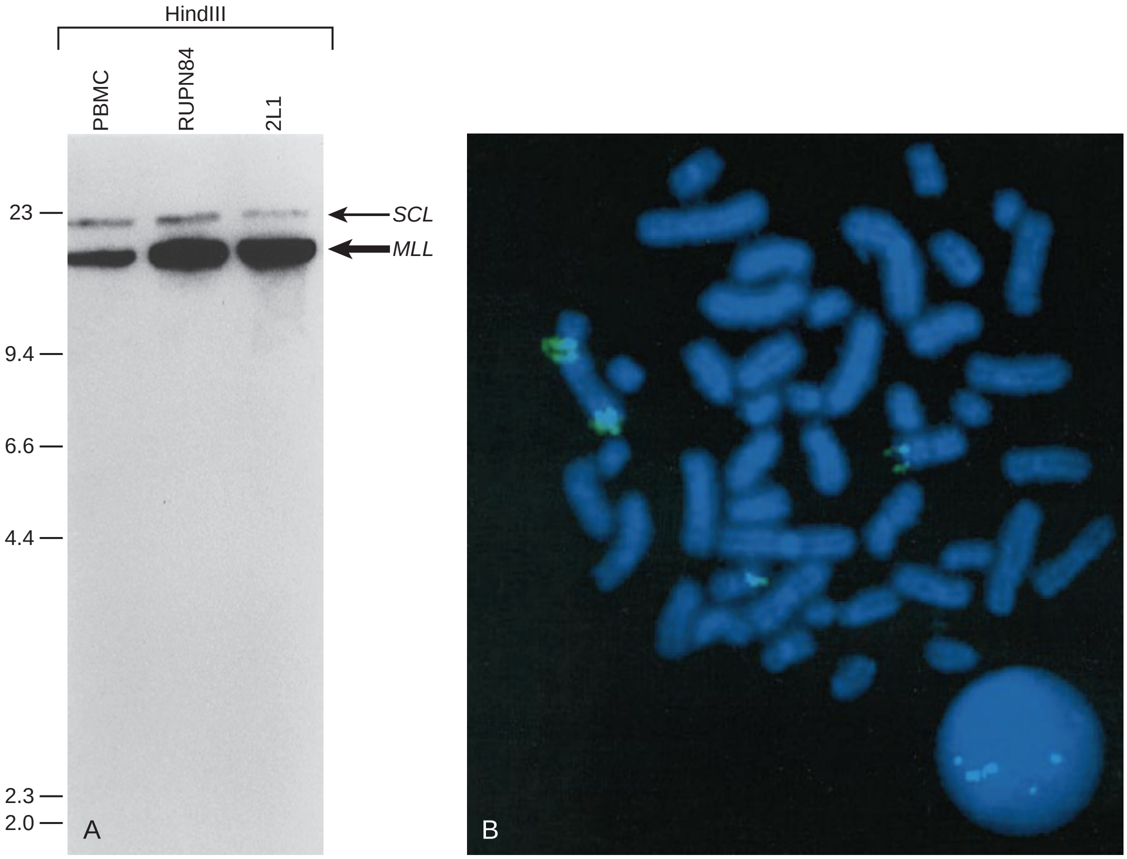

Figure 45-4 **A,** Southern blot analysis indicating *MLL* gene amplification in treatment-related acute myelogenous leukemia (AML). Southern blot analysis of *HindIII*-digested genomic DNA from French-American-British M4 AML cells (RUPN84) of a patient whose AML karyotype showed no evidence of chromosome band 11q23 rearrangement that would suggest *MLL* gene rearrangement and a cell line established from the same AML (2L1). Cohybridization with a *MLL* bcr-region probe and a loading control *SCL* probe demonstrates unrearranged but amplified *MLL* with signal intensity of 4.3 : 1 in the AML compared with normal peripheral blood mononuclear cell (PBMC) control DNA. **B,** Fluorescence in situ hybridization confirms *MLL* genomic amplification in RUPN84. *(Modified from Felix CA, Megonigal MD, Chervinsky DS, et al: Association of germline* p53 *mutation with* MLL *segmental jumping translocation in treatment-related leukemia.* Blood *91:4451–4456, 1998.)*

methods interrogate chromosomal regions of interest by using nucleic acid probes.[17,18] Most molecular cytogenetic methods use some variant of in situ hybridization (ISH), in which DNA probes are hybridized and evaluated in the cellular context. These probes are usually cosmids, containing an approximately 40-kb sequence of interest or bacterial artificial chromosomes, containing hundreds to a few thousand kilobases of sequence. ISH assays can be performed with fluorescence or enzymatic detection, referred to as FISH and CISH (chromogenic in situ hybridization), respectively (Figs. 45-5 and 45-6).[18]

Flexibility of in Situ Hybridization: Substrate Options. FISH and CISH analyses are performed routinely in cytogenetic preparations (metaphase spreads) and in paraffin sections and other archival pathologic preparations. Substantial advantages of using paraffin sections include the following: (1) the abundance of source material for each case permits retrospective and repeat analyses; and (2) the well-preserved cell morphology can guide evaluation of the chromosomal events in the relevant cell populations. However, a drawback in the use of paraffin sections is that the nuclei are generally incomplete, having been sliced through during preparation of the sections by microtomy.[19] This limitation can be addressed by performing the ISH assays with nuclei disaggregated from thick (50- to 60-μμ) paraffin sections[20] or from thin cores of the paraffin block.[21]

Resolution. Most ISH studies have a resolution of one to several megabases on metaphase spreads. Notwithstanding the aforementioned problems of interphase FISH on fixed material, the technique offers the advantage of higher resolution, given the less compact arrangement of DNA in interphase nuclei. Higher-resolution FISH techniques have been developed in which the DNA is essentially stretched out over a slide, as in direct visual hybridization (DIRVISH), resulting in a resolution of between 700 and 5 kb,[22] or fiber FISH, in which the resolution is between 500 kb and just a few kilobases.[23]

Highly Combinatorial Modifications of FISH. Various molecular cytogenetic methods have expanded the capabilities of FISH, enabling evaluation of the entire genome or karyotype. Examples include comparative genomic hybridization (CGH)[24,25] and spectral karyotyping (SKY).[26] CGH is performed by extracting total genomic DNA from a tumor of interest and from a nonneoplastic control cell population. These DNAs are differentially

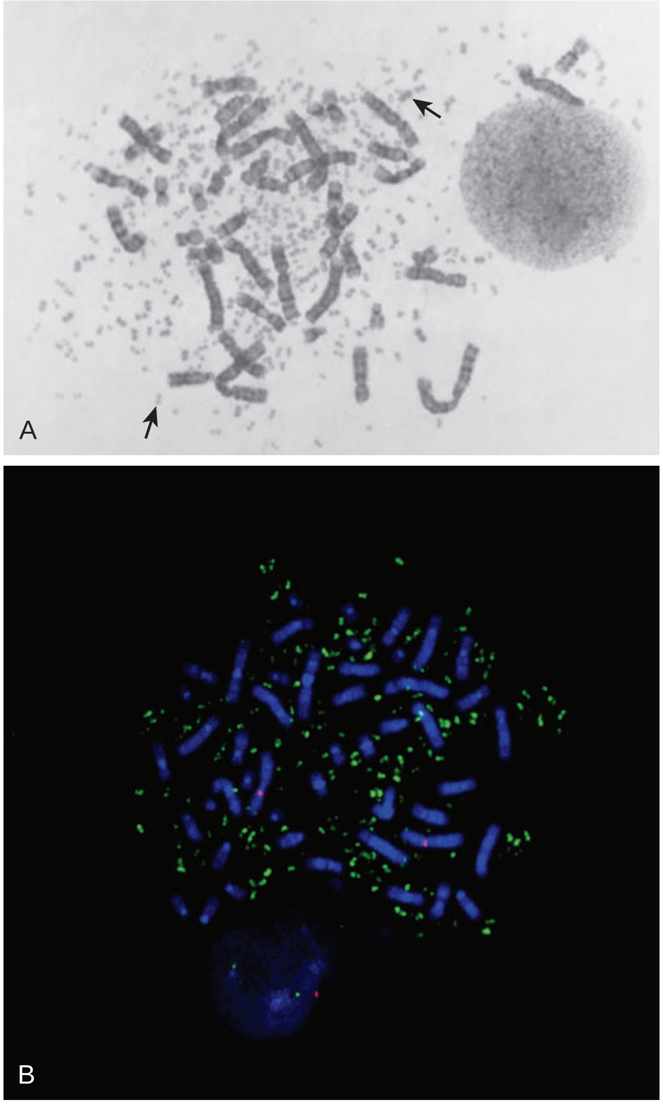

Figure 45-5 **A,** Giemsa-stained neuroblastoma metaphase cell (and with nucleus from a different cell on right) showing hundreds of variably sized double-minute chromosomes, as indicated by *arrows*. **B,** *MYCN* fluorescence in situ hybridization (FISH) evaluation of neuroblastoma metaphase cell, showing numerous extrachromosomal double minutes containing *MYNC (green)* whereas the reference chromosome 2 pericentromeric FISH probe *(red)* shows two copies.

labeled (e.g., tumor DNA with fluorescein and control DNA with rhodamine) and in the earliest applications were cohybridized against normal metaphase cells (metaphase CGH), although these methods have been rapidly supplanted by higher-resolution assays in which the sample DNAs are hybridized against arrayed clones (array CGH) or interrogated for presence of informative single nucleotide polymorphisms (SNPs) as an indicator of copy number and heterozygosity across the genome (discussed later).

An advantage of CGH, compared with conventional karyotyping, is that the tumor DNA can be isolated from frozen or even paraffin specimens, without any need for cell culture, thereby avoiding the selection pressures imposed by culture and instead capturing an overview of the in vivo situation, although diluted by the admixture of support stromal DNA. In addition, the array CGH methods (discussed later) can detect very small deletions, which would be overlooked by traditional cytogenetic banding assays and might even be missed by FISH. However, CGH does not detect the balanced chromosomal rearrangements, particularly the translocations that are the genetic hallmarks of many pediatric cancers. Furthermore, while detecting chromosomal amplifications and deletions reliably, the technique does not provide a functional assay in terms of expression level changes.

Genome-wide molecular cytogenetics can be performed using spectral karyotyping or M-FISH, in which entire panels of DNA probes are simultaneously hybridized against tumor metaphase cells.[26] Whereas conventional FISH techniques involve hybridization of one or two fluorescence-tagged probes, the spectral karyotyping and M-FISH methods use probes for each chromosome or chromosome arm (24 or more probes). Each probe is then detected combinatorially, using different ratios of fluorescence markers, such as fluorescein and rhodamine. By varying the ratio of fluorescence tags, each chromosome can be visualized with a unique color (Fig. 45-7). Thus spectral karyotyping enables a comprehensive ISH screen of the entire tumor cell karyotype. Spectral karyotyping and M-FISH are powerful research tools in tumor cytogenetics and have been useful in identifying rearrangements that are cryptic by conventional cytogenetic banding methods or that are highly complex.[27,28] However, these techniques have generally been supplanted by array CGH and SNP profiling methods (see later).

Routine Applications of FISH. Most ISH studies performed in clinical laboratories are focused on investigating deletions, rearrangements, or amplifications of particular gene loci or chromosomes. The probes used for

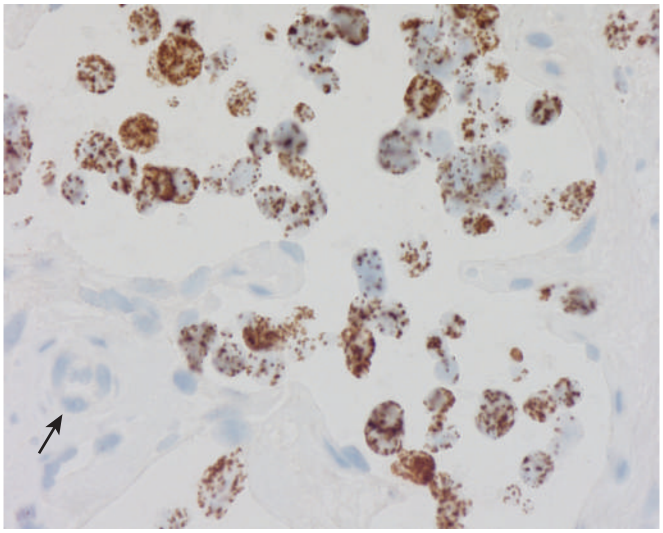

Figure 45-6 *MYCN* chromogenic in situ hybridization in a neuroblastoma paraffin section. Peroxidase-DAB detection *(brown)* of *MYCN* fluorescence in situ hybridization probe demonstrates high-level *MYCN* amplification in neuroblastoma cells but not in fibrovascular nonneoplastic cells *(arrow)*.

FISH analysis of chromosomal translocations (and other balanced cytogenetic rearrangements) generally fall into two categories. First, there are those that hybridize to a region spanning a breakpoint on one involved chromosome, producing a split signal in the presence of chromosomal rearrangement (see Fig. 45-2), Second, there are probes designed to come together in the presence of a fusion, in which a probe labeled with one fluorochrome hybridizes to one partner gene and the other, differentially labeled, to its fusion partner, with these producing a fused fluorescent signal only in the presence of a gene rearrangement.

Maximizing Data Yield from Individual FISH Probes for Rearrangements. Judicious selection of break-apart FISH probes can allow applicability to a wide variety of tumors, in which the probe interrogates a frequently rearranged gene such as *EWSR1* in various solid tumors or *MLL* in leukemias. The *EWS* gene undergoes rearrangement with various ETS family genes in Ewing sarcoma and *EWSR1* is rearranged in pediatric desmoplastic round cell tumors and clear cell sarcomas of soft parts, among others. Each of these diagnostically useful *EWSR1* rearrangements can be demonstrated using a single *EWSR1* break-apart FISH probe (Fig. 45-8), with ultimate diagnosis requiring interpretation of the molecular findings in the context of the histology.

Additional gross genetic aberrations routinely accompanying chromosomal translocation may be exploited to refine interpretation of FISH-based analysis in certain contexts. For example, *FOXO1* gene FISH can distinguish the *PAX7-FOXO1* and *PAX3-FOXO1* oncogenic fusions in alveolar rhabdomyosarcoma, given that the *PAX7-FOXO1* (but not the *PAX3-FOXO1*) is invariably highly amplified in these tumors. This distinction is warranted because of its prognostic significance. In the typical scenario, in which routine pathologic evaluation by light microscopy of hematoxylin and eosin (H&E)-stained sections with accompanying immunohistochemistry has generated a reasonably narrow differential diagnosis, genetic testing by this type of assay is highly informative and increasingly being used. Generally, this somewhat looser FISH-based assay may be regarded as having optimal attributes, providing greater sensitivity than karyotypic analysis and being capable of detecting cryptic or masked translocations[29] while not being burdened by the restrictive specificity of PCR-based assays, a feature that is especially advantageous for detection of variant translocations.

FISH in the Analysis of Gains and Losses. Although quantitative assessment of gene amplifications and deletions can be obtained by quantitative PCR (qPCR) or FISH, in practice such assays are more often conducted in clinical laboratories by FISH-based methods. In the example of *MYCN* amplification in neuroblastoma, FISH detection is performed routinely (see Figs. 45-5 and 45-6). Assessment of *MYCN* amplification may alternatively be done by semiquantitative PCR, using a standard PCR assay with normal (unamplified) and known amplified controls and multiplexing the reaction to include a housekeeping gene along with the gene of interest. However, such assessments can be confounded by intratumoral

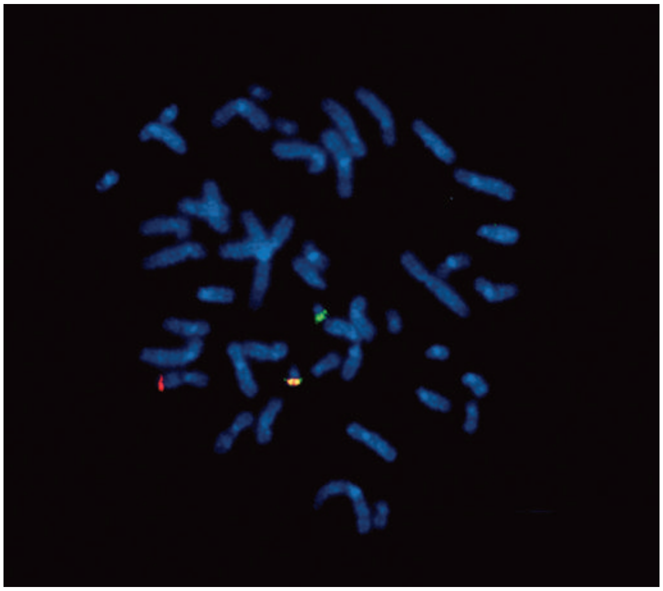

Figure 45-8 *EWS* break-apart fluorescence in situ hybridization probe, hybridized to Ewing sarcoma metaphase cell, in which probe components centromeric and telomeric to *EWSR1* are detected with fluorescein isothiocyanate *(green)* and rhodamine *(red)*, respectively. *EWSR1* rearrangement is indicated by the breaking apart of the normal yellow (*green-red fusion)* signal into the red and green components, which localize to different chromosomes as a result of translocation.

heterogeneity. In neuroblastoma, this heterogeneity may encompass substantial variations in cellular composition and maturation, and thus careful selection of tumor tissue for analysis is essential. The analysis of poorly selected tissue for *MYCN* evaluation (e.g., submission of schwannian stroma) will otherwise yield a false-negative result.[30] Moreover, contributions of different components of the neuroblastic tumor in the final DNA isolate can dilute out regional (neuroblast-specific) *MYCN* amplification, again yielding false-negative results. In this context, there is a distinct advantage to the FISH assays for *MYCN* amplification, because such methods permit correlation with cytology or morphology for the detection of regional heterogeneity of *MYCN* amplification, particularly when performed in tissue sections or multifocal touch imprints.

Detection of deletions by FISH is a more complex matter and particularly challenging when using fixed tissue, in which the assay is for an absence of signal and one is dealing with interphase nuclei, by definition incomplete (sliced through by microtomy), with an admixture of normal stromal cells further confounding the picture. Where cytogenetically abnormal metaphase spreads are available, these problems are largely circumvented, but there are other potentially more suitable technical strategies that might be used, including PCR-based assays—again with the caveat of normal cell admixture—to establish loss of heterozygosity (LOH). The immunohistochemical stain may provide a ready assay for such detection, as in the case of the *SMARCB1* gene on chromosome 22q, commonly deleted in malignant rhabdoid tumors (Fig. 45-9), and atypical teratoid rhabdoid tumors.[31]

Polymerase Chain Reaction–Based Molecular Assays

General Applications of PCR-Based Methods

Since the initial description of the basic PCR assay,[32] critical modifications of the technique have led to massive expansion of the applicability of this technology. The initial methodology involved the use of a DNA template from which a sequence of interest could selectively be amplified. This methodology provides the basis for testing for LOH, which relies on the natural allelic heterogeneity of repeat sequences in the vicinity of a gene of interest.[33] Where a genomic region is deleted, the concomitant loss of an adjacent allelic repeat sequence results in PCR amplification of only one version of the repeat sequence, thus producing hemizygosity (seeming homozygosity) at that locus.

Reverse-Transcriptase PCR Assay. When a particular question revolves around the presence of a specific transcript, the starting material is RNA, which is subjected to reverse-transcriptase PCR (RT-PCR), a highly sensitive technique.[34] The principle is that total RNA extracted from fresh, flash-frozen, or fixed material is reverse-transcribed into first-strand complementary DNA (cDNA). This provides the template[34,35] for testing for the presence of fusion oncogene transcripts using primers complementary to the involved partner genes flanking the fusion point in the chimeric transcript and which cannot therefore generate a product from unrearranged normal transcript. The technique is extraordinarily sensitive, able to detect as few as 1 in 10,000 cells bearing a fusion transcript.[36] The presence of just a small neoplastic component within a tissue sample for genetic testing is therefore sufficient for detection. Thus this PCR-based technology is useful for the detection of minimal residual disease[35] and well suited for the surveillance of hematologic malignancy, in which serial peripheral blood or bone marrow specimens are obtained for routine follow-up of patients. However, this same sensitivity of PCR-based methods carries with it the risk for false-positive results, from cross-contamination of minute amounts of fusion gene templates within assays or detection of very-low-level biologically insignificant fusion transcripts within specimens. Although moot in the context of demonstrating uniquely tumor-associated aberrations (e.g., fusion products), ideally DNAse I treatment of the RNA substrate should be performed to eliminate the possibility of inadvertent genomic amplification during RT-PCR.

Specificity of RT-PCR Reaction. Breakpoint variability within the genes involved in translocation-generated fusion oncogenes has prognostic implications in some cases. This is reported for Ewing sarcoma and synovial

sarcoma, in which a favorable prognosis is associated with a type I fusion of *EWS* exon 7 to *FLI1* exon 6 compared with all other combinatorial variations in Ewing sarcoma (Fig. 45-10).[37-39] *SYT-SSX2* fusion in synovial sarcoma is similarly reportedly associated with better patient outcome.[40,41] Assays may be designed to address breakpoint variability through choice of primers, selectively amplifying only one variant product, or by choosing consensus primers that will amplify several transcripts[42,43] and then sequencing the product to establish the precise nature of the transcript. An indication of transcript type might already have been obtained from gel electrophoresis demonstrating the product size (Fig. 45-11; see Fig. 45-10). PCR-based assays are best suited to the detection of such fine genetic detail, which cannot be detected by karyotypic analysis and only by specifically designed FISH assays. Currently, distinction among variant transcripts generally remains of academic interest because it provides no basis for therapeutic stratification.

In the case of *MLL* translocations, not only can one of more than 50 different partner genes be fused to *MLL* but it has also been suggested that the various partner genes of *MLL* affect the prognosis.[44] In this case, PCR

with gene-specific primers has been one approach to identify fusion transcripts involving some of the more common partner genes of *MLL*, and primer combinations for different *MLL* transcripts can be combined in a multiplex PCR reaction. This is most feasible in ALL, where the *MLL* partner genes are less heterogeneous than in acute myeloid leukemia (AML). Alternatively, approaches such as cDNA panhandle PCR can detect the fusion transcript produced by the 5′-*MLL* partner gene 3′ rearrangement using primer sequences derived from MLL. This is accomplished by the generation of a stem loop template in which a known *MLL* sequence has been attached to the unknown partner sequence by reverse transcribing the first-strand cDNA from total RNA using a 5′-*MLL*-random hexamer adapter-3′ primer for the primer extension.[45]

Additionally, genomic panhandle PCR approaches[46-48] and long distance inverse PCR approaches[49,50] are alternatives for characterizing translocations in which the sequence of only one of the involved genes is known. And increasingly, intron-capture methods, coupled with sequencing, are used in high-throughput sequencing screens to identify oncogene fusion partners.

One clinical scenario that requires the ability to detect a broad range of chromosomal translocations, including unknown or rare fusion variants, is in surveillance screening for evidence of a preleukemic state in chemotherapy-exposed patients, before these patients manifest frank secondary leukemia.[51] Advances in sensitive molecular PCR-based screening methods and molecular cytogenetic screening methods such as FISH will better enable the prospective detection of chromosomal translocations, which is crucial in such applications.

Quantitative PCR Assay. Simultaneous PCR of a constitutively expressed housekeeping gene provides an internal control. A standard positive control may be used as a comparator across a series of cases to rank these in a semiquantitative approach.[52] Use of qPCR methods can provide precise information about the actual copy number of oncogene transcripts (gene expression level) by qRT-PCR or gene copy number when genomic DNA is used as template material. qPCR has advantages of increased reliability and reproducibility over conventional PCR. Because it provides data accrued during the entire cycle, rather than just end-point analysis, as in standard PCR, it will discriminate between different assays quantitatively rather than based on product size differences. Additionally, the graphic readout of accumulating fluorescence generated within each tube or well during the reaction is instantaneous (real time) and therefore no delaying additional step for product analysis is

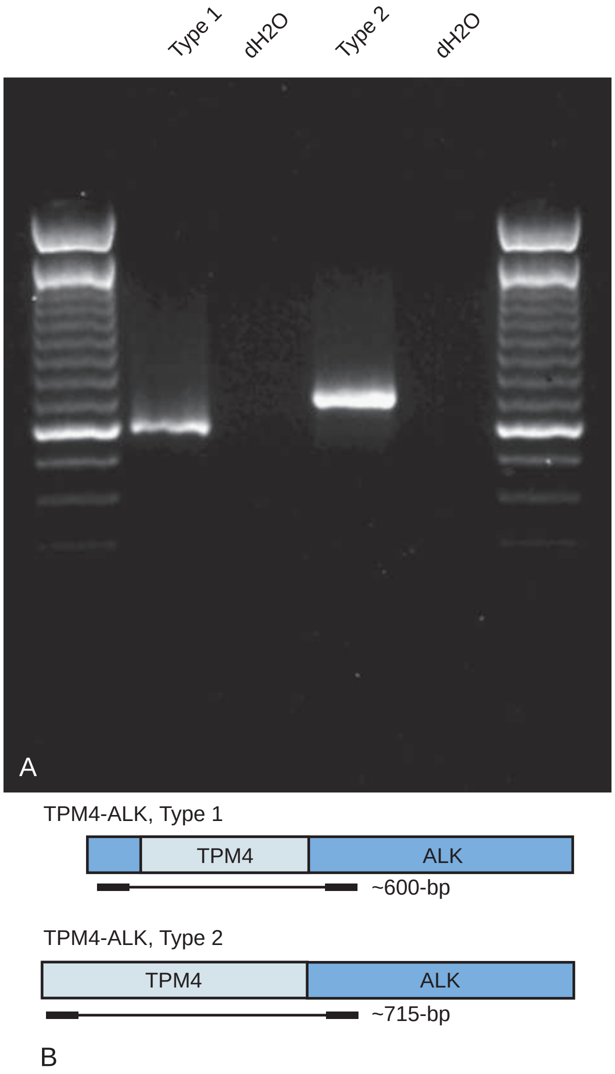

Figure 45-11 Reverse-transcriptase polymerase chain reaction (RT-PCR) demonstration of various *TPM4-ALK* fusion oncogene transcripts in inflammatory myofibroblastic tumors, as distinguished by gel electrophoresis of PCR products generated with the same primers (**A**), with primer hybridization sites as indicated (**B**).

required. In conventional PCR, the amplification products must typically be evaluated by gel electrophoresis. Therefore the assay turnaround time is minimized in qPCR, so that a complete analysis can be performed in only a few hours. qPCR is more sensitive, with an ability to detect twofold changes in expression level as opposed to a tenfold cutoff for standard PCR assays. If desired, the products can still be subjected to gel electrophoresis (e.g., to evaluate product size). Various forms of qPCR are available, including (1) an SYBR green-based method, detecting double-stranded DNA product accumulation by binding to the minor groove of double-stranded DNA nonspecifically and thus being more readily subject to false positivity because of contamination or detection of primer-dimer; and (2) TaqMan methodology, based on highly specific primer-probe combinations. In TaqMan qPCR, a probe labeled with a fluorescent dye at one end (5′) and a quencher at the other (3′) is designed to bind within the sequence amplified by qPCR. In the unbound state, the proximity of quencher to the fluorescent dye inhibits detection of the fluorescence through Foerster resonance energy transfer (FRET). Once the probe has bound within the amplified sequence, 5′ exonuclease activity of the polymerase enzyme leads to probe cleavage and dissociation of fluorescent dye and quencher, with ensuing accumulation of fluorescence proportional to product amplification (strictly probe cleavage). Multiplexing of reactions is possible with TaqMan but not SYBR green technology.

Array Comparative Genomic Hybridization and Single Nucleotide Polymorphism Profiling Assays

Conventional metaphase CGH, which was summarized previously, was made obsolete by the advent of array CGH, in which the tumor DNA is hybridized instead to high-density arrays of probes covering the entire genome.[53] Array CGH provides a much higher-resolution genome-wide definition of genetic gains and losses. However, conventional and array-based CGH do not detect balanced chromosome translocations, a hallmark of many pediatric cancers. Genome-wide SNP assays (Fig. 45-12), like array CGH, are used increasingly as a higher-resolution alternative to conventional karyotyping for genome-wide assessments of gene copy number alterations, and, unlike array CGH, the SNP methods have the advantage of demonstrating LOH, even in situations in which gene copy number is normal (copy number neutral LOH). However, SNP profiling generally provides less quantitative assessment of copy number gains compared with array CGH.

Next-Generation Sequencing and Other Techniques

In light of the ever-increasing number of gene fusions identified in pediatric sarcomas and hematologic neoplasms, the need for more efficient, multiplexed methods for their detection is becoming more pressing. Increasingly, molecular diagnostic laboratories are implementing variations of next-generation sequencing toward these ends. Whereas few laboratories now employ comprehensive genome sequencing (exome, whole genome, or whole transcriptome) in routine diagnostics, more targeted high-throughput sequencing panels have become commonplace. Typically, these panels focus on gene perturbations with known prognostic, predictive, or diagnostic relevance in cancer, detecting hundreds of clinically relevant mutations in a single panel. Although the translation of these new approaches based on next-generation sequencing into routine diagnostic assays is moving quickly,[54] there remain challenges to routine implementation for diagnosis, including the need for relatively large amounts of high-quality nucleic acids. In addition to next-generation sequencing, there are various other novel and promising methods for detecting the ever-expanding variety of diagnostically relevant gene rearrangements in cancer. These include the NanoString nCounter system, which detects individual messenger RNA (mRNA) molecules without PCR amplification in a quantitative and highly multiplexed fashion[55] and antibody detection of translocations assays.[56]

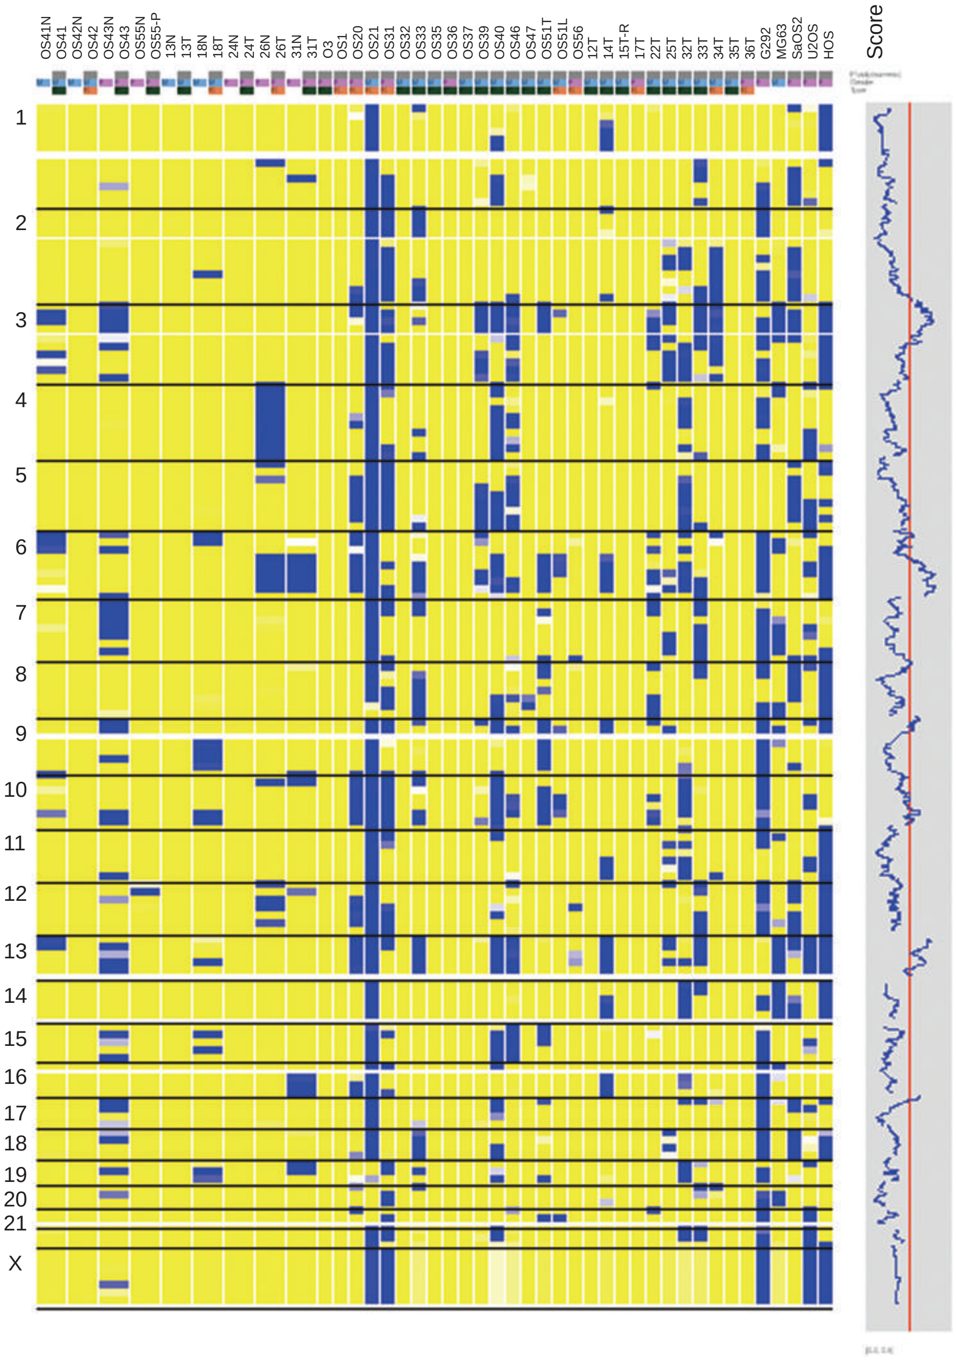

Figure 45-12 Genome-wide single-nucleotide polymorphism (SNP) analysis of osteosarcomas, with each column showing data from an individual case and the rows showing SNP data for each chromosome. Most osteosarcomas have numerous regions of SNP loss of heterozygosity, which are indicated in *blue,* whereas admixed regions of retained heterozygosity are in *yellow.*

It might be surmised that the optimal setup of a tumor genetics laboratory in the pediatric context would strive to culture cells from all newly diagnosed tumors. It would largely rely on FISH-based assays to screen for rearrangements or amplifications of commonly involved genes such as *EWSR1*, *FOXO1*, *MYCN*, *MLL*, and *ALK* but retain expertise in PCR for detection of gene rearrangements and minimal residual disease and array-based or sequencing screens for more comprehensive evaluations of actionable mutations across the broad spectrum of pediatric hematologic neoplasms and solid tumors.

GENOMIC MECHANISMS IN PEDIATRIC TUMORS

The cytogenetic aberrations in pediatric tumors can be extremely simple, involving loss or rearrangement of only a single chromosome, or can be highly complex, as manifested by a karyotype showing dozens of abnormal chromosomes. Complexly abnormal pediatric cancer karyotypes, containing 10 or more clonal rearrangements, are most often found in highly malignant solid tumors, such as osteosarcoma. On the other hand, a subset of highly malignant solid tumors, such as Ewing sarcoma and synovial sarcoma, has noncomplex karyotypes. Therefore the absence of cytogenetic complexity is not, in itself, a reassuring finding.

Clinically relevant chromosomal aberrations in pediatric tumors result in amplification, translocation, or deletion of various target genes. Amplifications, manifest as intrachromosomal homogeneously staining regions or extrachromosomal double minutes (see Fig. 45-5), are of greatest clinical relevance in neuroblastoma. They are also seen frequently in subsets of rhabdomyosarcoma, osteosarcoma, and central nervous system (CNS) tumors[57,58] and in leukemia, in which DNA segments encompassing various amplified oncogenes can be translocated to different regions of the genome. This phenomenon is termed *segmental jumping translocation.*[16,59] Deletions are generally believed to target tumor suppressor gene loci. Although of limited ancillary diagnostic value, detection of deletions may have prognostic implications (see Tables 45-1 and 45-3). Chromosomal translocations are particularly frequent in leukemias, lymphomas, and sarcomas, where they typically create fusions of regulatory or coding sequences in genes located at the breakpoints of the participant chromosomes.[60,61] Translocations result from double-strand DNA breaks, which are believed to occur more frequently in cancer cells than in normal cells, presumably as a manifestation of the genetic instability that is characteristic of many cancers. Most random translocations arising in cancer cells do not create functionally significant oncogenes and are therefore not selected for and retained by most of the cells in that cancer. The cytogenetic evidence suggests that at most a limited variety of translocations serve an oncogenic role in any given type of pediatric cancer. Many such recurring translocations have clinical use as diagnostic biomarkers (see Tables 45-1, 45-2, and 45-3) or for identifying tumor-specific therapeutic targets (see Tables 45-1 and 45-3).

Some translocation breakpoints directly interrupt the coding sequences of the target genes, leading to the creation of a fusion oncogene. Other breakpoints are outside of the gene coding sequences but nonetheless alter transcriptional regulation of the target gene. In the case of coding sequence fusions, important functional domains from the two component genes are generally brought together by the chromosomal rearrangement. For example, fusion kinase oncogenes often result from apposition of the kinase gene catalytic domain with a translocation partner's protein-protein association domain (oligomerization domain). Such fusions lead to constitutive activation of the kinase. In other translocations, the intact coding sequence of a particular gene, usually one expressed at weak to undetectable levels in the nonneoplastic progenitor cell, is overexpressed by translocational juxtaposition to highly active promoter and enhancer sequences. One well-known example occurs in Burkitt lymphomas, in which *MYC* oncogene expression is increased by translocation into various transcriptionally active *IG* gene regions. The following sections review considerations of causative factors for translocation-associated oncogenes and provide key examples of their structural and functional roles in pediatric cancers.

Causes and Predisposing Factors for Chromosomal Translocations

The underlying mechanisms responsible for the genesis of chromosomal translocations are still poorly understood, but DNA double-strand breakage is a key step in this process. This may be induced by intracellular (endogenous) or extracellular (exogenous) agents. Some endogenous processes associated with double-strand breakage include V(D)J recombinase-mediated intrachromosomal rearrangements at *IG* or *TCR* loci, meiotic recombination between homologous chromatids, topoisomerase II (TOP2)–mediated changes in DNA topology that are required for DNA strand passage during mitosis and for the relaxation of supercoiled DNA for RNA transcription, and production of DNA-damaging agents (e.g., oxygen free radicals) from spontaneous hydrolysis, which themselves can alter DNA topology. Among the many exogenous insults causing double-stranded DNA breakage, ionizing radiation is the most extensively studied and has been shown to disrupt hydrogen bonds and sugar-phosphate backbones, damage purine and pyrimidine bases, and induce cross-links between DNA strands. Such damage can lead to single- or double-strand DNA breakage. Notably, the locations of chromosomal breakage induced by ionizing radiation are not entirely random. Rather, smaller chromosomes appear to be disproportionately affected, as are regions rich in GC repeats. Other inducers of chromosomal breakage include ultraviolet A–activated psoralens, chemotherapeutic agents, and DNA endonucleases.

One class of chemotherapeutic agents that can induce chromosomal breakage is the alkylating agents, such as nitrogen mustards, mitomycin C, nitrosoureas, and platinum compounds, which form DNA adducts and cause intrastrand and interstrand DNA cross-linkage. DNA damage caused by treatment with these agents is associated with secondary myelodysplastic syndrome (MDS) and secondary leukemias, whose salient molecular cytogenetic features include complex numerical and structural abnormalities that often involve loss of chromosome 5, 5q, 7, or 7q. Noteworthy also is that germline and somatic mutations in the TP53 tumor suppressor protein, which is critical for DNA damage recognition, are frequent in secondary leukemias with chromosome 5q abnormalities and a complex karyotype, suggesting that genomic instability caused by loss of TP53 predisposes to this treatment complication.[16,62] The second class of chemotherapeutic agents that can induce chromosomal breakage are the TOP2 poisons, which target the nuclear enzyme topoisomerase II (e.g., the epipodophyllotoxins etoposide and teniposide; the anthracyclines doxorubicin, daunorubicin, and idarubicin; the anthracenedione mitoxantrone; and the combined topoisomerase I/topoisomerase II poison dactinomycin).[63]

Studies on genomic instability mechanisms in the yeast *Saccharomyces cerevisiae* have implicated defects in double-strand DNA breakage repair as causative factors in chromosomal translocations.[64] These repair defects can involve homologous recombination repair or nonhomologous end joining. Homologous recombination repair necessitates guidance of the DNA repair mechanism by two homologous sister chromatids and is therefore more active in the G2 and S phases of the cell cycle. Nonhomologous end joining is intrinsically mutagenic and does not require extensive homology (usually <10 base pairs [bp]) between the two sequences that are joined. Nonhomologous end joining does not require the presence of guiding sister chromatids and is therefore most active during the G1 phase of the cell cycle. Malfunction of these DNA repair systems is responsible for the chromosomal instability in some cancer and premature aging syndromes such as Bloom syndrome, an autosomal recessive disorder caused by inactivating mutations of the *BLM* gene. *BLM* encodes a nuclear protein related to the RecQ family of helicases, which are DNA-unwinding proteins involved in homologous recombination. Bloom syndrome patients show increased rates of chromosomal breakage and exhibit sister chromatid exchanges in the form of quadriradials, which are four-armed structures composed of two chromosomes intersecting at regions of chromatin homology. Bloom syndrome patients develop various benign and malignant tumors, generally occurring at an earlier age than in the normal population.

Other chromosomal instability syndromes result from defects in RecQ helicase proteins. For example, both Werner and Rothmund-Thompson syndromes are autosomal recessive disorders with germline mutations of *RECQL2 (WRN2)* and *RECQL4 (WRN4)*, respectively. Affected individuals develop various tumors, with osteosarcomas being particularly characteristic of patients with the Rothmund-Thompson syndrome. Ataxia-telangiectasia is an autosomal recessive disorder conferring exquisite sensitivity to ionizing radiation.[65] Ataxia-telangiectasia generally results from mutations in the *ATM* gene, which encodes a protein kinase that participates in surveillance for double-strand DNA breakage. Lymphocytes from ataxia-telangiectasia patients show increased levels of chromosomal rearrangement.

Nijmegen breakage syndrome shares several features with ataxia-telangiectasia but is caused by mutations of the *NBN (NBS1)* gene. The NBN (NBS1) protein participates in a complex with apparent roles in homologous recombination repair and nonhomologous end joining. Patients with ataxia-telangiectasia and Nijmegen breakage syndromes are particularly susceptible to the development of leukemias and lymphomas.

Fanconi anemia is a heterogeneous group of autosomal recessive disorders with predisposition to cancer, particularly leukemias and squamous cell carcinomas. At least eight distinct genes involved in DNA double-strand breakage repair have been implicated in the genesis of Fanconi anemia.[66] The chromosomes of patients with Fanconi anemia exhibit increased sensitivity to DNA cross-linking agents, such as diepoxybutane, and this feature can be useful in diagnosis of the disease. Fanconi anemia DNA repair defects can also result from germline mutations of the *BRCA2* gene.

The Li-Fraumeni syndrome is a familial cancer predisposition syndrome that manifests as early onset of a constellation of tumors (rhabdomyosarcoma, breast carcinoma, osteogenic sarcoma, astrocytic brain tumors, adrenal cortical carcinoma, acute myelogenous leukemia) caused by germline mutation in the TP53 tumor suppressor protein.[67]

Certain DNA sequences may be targeted for chromosomal rearrangements. For example, certain sequences within the *MLL* transcription factor gene might comprise TOP2 DNA-binding sites that promote leukemia-associated rearrangements, and this has been studied in detail.[68] Notably, *MLL* is typically rearranged in secondary leukemias after exposure to topoisomerase II poisons, including epipodophyllotoxins, and in leukemia in infants in whom maternal-fetal exposures to dietary or environmental topoisomerase II poisons have been implicated.[63] Even though there is not a clear consensus TOP2 DNA-binding sequence in *MLL* and the preferred sites of enzyme recognition are modified by specific chemotherapeutic agents, it has been shown that *MLL* translocation breakpoints occur near functional sites of chemotherapy-enhanced TOP2 cleavage in in vitro assays.[63] TOP2 is an essential cellular enzyme that relaxes supercoiled DNA by transiently cleaving and religating both strands of the double helix. TOP2 catalyzes the sequential reactions of double-strand DNA cleavage, DNA strand passage, and DNA strand rejoining (religation). The DNA cleavage reaction occurs when each subunit of the TOP2 enzyme homodimer covalently attaches to and introduces staggered nicks in the DNA, with the nicked DNA remaining tethered to the enzyme subunits, forming a fleeting TOP2/DNA intermediate called the cleavage complex. Particular anticancer drugs such as etoposide alter the cleavage-religation equilibrium by decreasing the rate of religation, which damages the DNA by increasing cleavage complexes. Chemotherapeutic agents that interact with TOP2 in this manner are termed *topoisomerase II poisons* because the enzyme is converted to a cellular toxin that promotes strand breakage. Although sometimes called TOP2 inhibitors when used clinically, these agents are distinct in their activity from catalytic inhibitors of this enzyme. The association of various chemotherapeutic TOP2 poisons used for anticancer treatment with secondary leukemias characterized by balanced chromosomal translocations has suggested that TOP2 has a role in other balanced translocations, such as t(8;21), t(15;17), and inv(16) in addition to those involving *MLL*.

Other examples of recombination-promoting sequences are the heptamer-nonamer sequences adjacent to translocation breakpoints in many B-cell lymphomas. These sequences serve as sites of V(D)J recombination and are, therefore, recombination signals in the B-cell context. Similarly, the sites of V(D)J recombination also promote translocations of *TCR* genes with heterologous gene loci in T-cell ALL and T-cell lymphomas.

Physical proximity of genes in interphase nuclei has also been implicated in their incorporation into fusion genes. For example, radiation-induced thyroid carcinomas frequently exhibit rearrangements of the protein tyrosine kinase gene *RET* on chromosome 10q11, which is most often fused with the *H4* locus, telomeric (band 10q21) to *RET* on the same chromosome arm.[69,70] *RET* and *H4* are physically juxtaposed in 35% of normal human thyroid cells, providing a hypothesis as to why these two particular genes are disproportionately likely to be fused after radiation-induced double-strand DNA breakage.[71] Indeed, the three-dimensional topography of the genome explains why certain rearrangements, particularly between neighboring regions on a given chromosome, are commonplace both in cancer and nonneoplastic cells.[72] Accordingly, whole transcriptome evaluations in various cancers have revealed hundreds of apparent intrachromosomal rearrangements in a given tumor, many of which involve closely neighboring genome regions and most of which are unlikely to create functionally important oncogenes. The constraints of genome organization and nuclear proximity likely determine that certain genes are the favored partners in cancer-associated rearrangements, even in situations in which other members of the same gene family would appear to be equally suitable, biologically, in the oncogenic roles. As one example, *MYC,* rather than its biologically similar family member, *MYCN,* is rearranged with an *IG* locus in Burkitt lymphoma; however, *MYCN* if moved to the *MYC* genomic locus effectively undergoes oncogenic rearrangement with *IGH.*[73]

One intriguing aspect of cancer chromosomal translocations is that they are sometimes amplified, providing additional copies of the associated fusion oncogenes. After their formation, the translocation breakpoint regions can be amplified as tandem repeats within the original chromosome or can be amplified as extrachromosomal structures, such as double-minute chromosomes. One example of intrachromosomal amplification occurs with the typically low-level amplification of *PDGFB* fusion genes in the spindle cell sarcoma dermatofibrosarcoma protuberans (Fig. 45-13, *A*).[74,75] An example of extrachromosomal amplification is found in a subset of alveolar rhabdomyosarcomas, in which double-minute chromosomes contain numerous copies of the *PAX7-FOXO1* fusion oncogene (see Fig. 45-13, *B*).[76] In either of these situations, the amplification event suggests that multiple copies of the fusion oncogenes are required to accomplish cellular transformation.

The *EWSR1* gene is rearranged in a striking number of pediatric sarcomas including Ewing sarcoma and desmoplastic small round cell tumor. There are, however, striking racial discrepancies with respect to Ewing sarcoma incidence, such that children of European ancestry are affected with a higher frequency than African-American, Asian, or Native American children. A recent study has shown, however, that the incidence of EWSR1-rearranged sarcoma is not uniformly higher in European descendants, because desmoplastic small round cell tumor (DSRCT), for example, occurs with higher frequency in African-American children.[77]

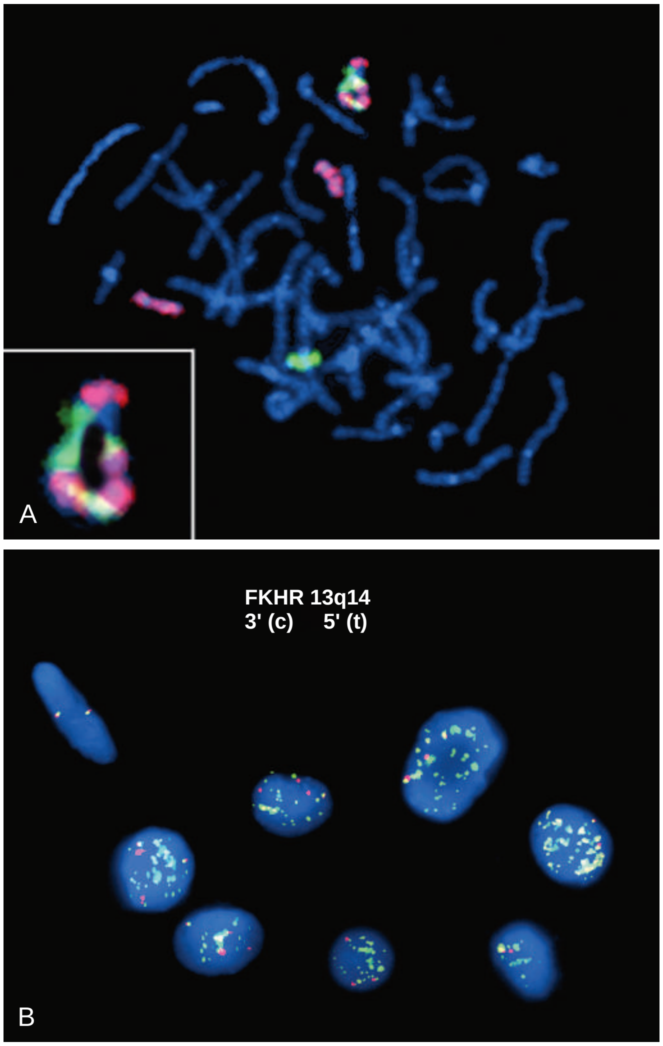

Figure 45-13 **A,** Fluorescence in situ hybridization (FISH), with whole chromosome "painting" probes to chromosomes 17 *(pink)* and 22 *(green),* demonstrates alternating segments of chromosomes 17 and 22 in a dermatofibrosarcoma protuberans ring chromosome *(magnified in inset),* resulting in threefold amplification of the characteristic *COL1A1-PDGFB* fusion oncogene. **B,** FISH demonstration of highly amplified and rearranged *FOXO1* gene *(green)* in an alveolar rhabdomyosarcoma with *PAX7-FOXO1* oncogenic fusion. Break-apart probe components 5′ and 3′ to the *FOXO1* gene are *red* and *green,* respectively. Normal fibroblast nucleus at upper left contains two normal fusion probe signals.

BIOLOGIC CONSEQUENCES OF CHROMOSOMAL TRANSLOCATION

Chromosomal Rearrangements Involving Transcription Factor Genes

Transcription factors are a heterogeneous group of DNA-binding proteins, most of which have domains involved in DNA binding, protein dimerization (for interaction with homologous proteins), and gene transactivation (for activation of gene transcription) or transcriptional repression. There are several classes of transcription factors, primarily relating to the structure of their DNA-binding domains. Some of the major categories include homeodomain proteins, zinc finger proteins, leucine zipper proteins, forkhead proteins, and helix-loop-helix proteins. Transcription factor genes are disrupted by many chromosomal translocations, resulting in their aberrant expression and function. Often, these transcription factor genes control lineage-specific developmental pathways and their abnormal activation can induce ectopic or asynchronous expression of corresponding lineage-specific antigenic markers, which then become a defining aspect of the transformed phenotype.

Many chromosomal translocations involving transcription factors have been described in leukemias and lymphomas. Chromosomal translocations in leukemias often interfere with the normal differentiation program of myeloid and lymphoid lineages,[78] although the presence of a chromosomal translocation per se does not prevent subclone evolution via further lineage-associated differentiation (e.g., progression from *IGH* gene rearrangement only to *IGH* plus *IGL*-chain rearrangement in precursor B-cell ALL). In acute leukemias, the targets for various chromosomal translocations are genes encoding hematopoiesis-related transcription factors, including AML1 (also known as RUNX1) and CBFB (see Fig. 45-12).

AML1 is a DNA-binding protein with significant homology to the *Drosophila melanogaster* developmental protein Runt. AML1 binds to the DNA enhancer sequence TGTGGT; the DNA-binding capabilities of AML1 are enhanced through interactions with the non–DNA-binding protein subunit of CBF (core-binding factor) called CBFB, thereby regulating expression of several genes involved in hematopoiesis. One of the most common chromosomal translocations observed in AMLs (approximately 12% of cases) is the t(8;21)(q22;q22), which fuses *AML1* on chromosome 21q to *RUNX1T1 (ETO)* on chromosome 8.[79] *ETO* encodes a nuclear phosphoprotein expressed in the nervous system and in CD34+ hematopoietic progenitor cells. ETO is a transforming protein that normally participates in a multiprotein complex involved in chromatin remodeling and transcriptional repression. The fusion protein AML1-ETO retains the Runt domain of AML1 and almost the entire sequence of ETO.[80] It appears that the ETO domains incorporated into the fusion oncoprotein can dominantly repress transcription of certain genes, the expression of which is normally activated by AML1. As an example, the tumor suppressor protein p14^{ARF} normally is transcriptionally activated by AML1, but p14^{ARF} is transcriptionally repressed by AML1-ETO.[81,82] *AML1* is also involved in several other chromosomal translocations in leukemias and myeloproliferative disorders, including *AML1-MDS1* in myelodysplastic (preleukemic) syndromes, *AML1-EVI1* in chronic myelogenous leukemia in blast crisis, and *TEL (ETV6)-AML1* in pre-B ALL. All these fusion genes retain the AML1 Runt domain.[83]

Another example of a fusion gene affecting the normal function of the AML1-CBFB DNA-binding transcription factor protein complex is *CBFB-SMMHC,* which results from rearrangement of chromosome 16 in the French-American-British (FAB) M4Eo subtype of AML.[84] *CBFB-SMMHC* can result from translocation or pericentric inversion of chromosome 16, thereby fusing sequences from the 5′ end of *CBFB* to the 3′ end of *SMMHC.* The resultant fusion oncoprotein contains the AML1-binding heterodimerization domain of CBFB juxtaposed to the coiled-coil domains of the MYH11 (SMMHC) protein. The fusion protein CBFB-SMMHC binds to the AML1 Runt domain more effectively than the normal CBFB and has a dominant negative effect on the AML1-CBFB complex.[85]

MLL is a transcription factor protein in which the amino and carboxyl aspects contribute transcriptional repression and activation activities, respectively. MLL undergoes posttranslational processing so that the transcriptional repression and activation regions are separated by cleavage, but they then reassociate with one another in a large multiprotein chromatin remodeling complex. MLL maintains but does not initiate expression of its target genes via histone methyltransferase activity, which is provided by a SET domain within the MLL carboxyl terminus.[86] A wide range of MLL fusion oncoproteins resulting from translocations of the *MLL* gene at chromosome band 11q23 contain the amino terminus of the MLL transcription factor and the carboxyl terminus of partner proteins that are themselves involved in transcriptional regulation. However, there is substantial diversity in MLL partner protein function and not all MLL partner proteins are transcription factors.[86]

Chimeric (fusion) transcription factor oncogenes are also featured in many soft tissue tumors. A much-studied example is the *EWS-FLI1* fusion oncogene resulting from the t(11;22)(q24;q12) translocation[87] in Ewing sarcoma. This translocation fuses *EWS* 5′ sequences to *FLI1* 3′ sequences. *EWS* encodes a ubiquitously expressed protein involved in DNA transcription, and *FLI1* is a member of a large family of DNA transcription factors that contain the highly conserved ETS domain. The *EWS-FLI1* fusion oncogene structure varies, depending on which *EWS* and *FLI1* exons are retained in the chimeric gene (see Fig. 45-10). *EWS* can be fused with other ETS family members to provide the oncogenic impulse in Ewing sarcoma, and, alternatively, *FUS* (an EWS family member) can instead be fused with ETS family members in Ewing sarcomas. EWSR1-ETS fusion proteins are necessary but insufficient for cellular transformation,[88,89] a process for which IGF1R is vital.[90] Some progress has been made in recent years in understanding the oncogenic mode of action of the EWSR1-ETS fusion protein, with a rather complex and multifaceted picture emerging whereby gene targets may be direct or indirect and include transcriptional regulators such as EZH2,[89,91] NROB1,[92] and NKX2.2,[93] as well as genes involved in signal transduction or genes involved in cell cycle control. EWS-FLI1 can directly bind promoters of target genes and modulate gene expression[94,95] by upregulating (e.g., IGF1, CCND1, hTERT[96]) or repressing targets (e.g., cyclin-dependent kinase inhibitors and IGFBP3, the latter potentially allowing increased IGF1 signaling). Reduced target expression may result from decreased transcription through EWS-FLI1 reducing Pol II at the target gene promoter or through posttranscriptional reduction of transcript half-life.[97] Any additional posttranscriptional role, for example, of microRNAs putatively targeted by the fusion oncogene remains to be elucidated fully,[98] and there is emerging evidence that posttranslational protein modification is a further important function of *EWS-ETS* fusions. The direct binding of EWSR1-ETS to the *EZH2* promoter specifically with upregulation of EZH2 is interesting in relation to the ongoing debate regarding the cell of origin of Ewing sarcoma. EZH2 is a subunit of the Polycomb repressor complex, PRC2, and its expression holds cells through reversible epigenetic means, in an undifferentiated state of "stemness."[99]

Similarly, *EWS* or *FUS* is fused with other genes (not belonging to the ETS family) in various Ewinglike and frankly non-Ewing mesenchymal small round blue cell neoplasms, always resulting in fusion oncoproteins with EWS or FUS at the amino-terminal end of the fusion protein. DSRCT, a clearly defined tumor that is considered absolutely distinct from Ewing sarcoma, is an exceptionally malignant cancer composed of nests of small round tumor cells sharply delineated by a reactive fibroblastic proliferation. It is cytogenetically characterized by t(11;22)(p13;q12), which fuses *EWS* to the *WT1* gene.[100] The EWS-WT1 fusion oncoprotein retains the EWS transactivation domain and the WT1 DNA-binding domain. *WT1,* located on chromosome 11p13 encodes a zinc finger transcription factor with crucial roles in genitourinary tract development. Germline *WT1* mutations cause Wilms tumor syndromes, including Denys-Drash and WAGR (*W*ilms-*A*niridia-*G*enitourinary abnormalities and mental *R*etardation) syndromes. Further examples of fusion genes involving *EWSR1* or *FUS* and non-ETS genes include isolated cases or small cohorts of small round blue cell tumors, which to a variable degree share histologic features with Ewing sarcoma. The partner genes may again be transcription factors, as seen with POU5F1 or NFATc2,[101,102] or in the case of SMARCA5,[103] a chromatin remodeler, whereas single reports each of a small round blue cell tumor with EWS-SP3[104] and of EWS-ZSG[105] represent fusions of EWS with zinc finger proteins. The latter case particularly has more similarity with DSRCT, insofar as it failed to react with CD99, a classic marker of Ewing sarcoma, but did express desmin. Indeed with respect to both these cases, fusion with a zinc finger gene resonates with the situation in DSRCT. The rarity of such cases precludes major comment on their likely biologic relationship with Ewing sarcoma versus DSRCT.

A recently described undifferentiated small round cell tumor is characterized by recurrent chromosomal translocations t(4;19)(q35;q13.1) or t(10;19)(q35;q26) fusing the high mobility group box [HMG] transcription factor *CIC* with one or other of the *DUX4* double homeobox transcription factor genes located within macrosatellite repeats on 4q and 10q[106]; thus these tumors are known as CIC-DUX4 tumors. An isolated report documenting t(18;19)(q23;q13.2) in a soft tissue tumor resembling Ewing sarcoma most likely represents a variant also involving *CIC.*[107]

Tumors of epithelial differentiation (carcinomas) often have complex karyotypes, which can obfuscate recurrent translocations. However, translocations involving transcriptional regulatory genes have been identified in several pediatric carcinomas, including follicular thyroid carcinomas, renal cell carcinomas, and NUT midline carcinoma.[108,109,110] Follicular thyroid carcinomas can feature *PAX8-PPARγ* fusion transcription factor genes resulting from t(2;3)(q13;p15)[108] (Fig. 45-14), whereas in the highly lethal NUT midline carcinomas, the translocation t(15;19)(q13;p13) (Fig. 45-15) results in oncogenic fusion of the bromodomain transcriptional regulator *BRD4* with a novel testis-restricted gene, *NUT.*[110] Although exhibiting epithelial immunophenotypic features, NUT midline carcinomas typically have a primitive round cell morphology (see Fig. 45-15).

Chromosomal Rearrangements Involving Protein Tyrosine Kinase Genes

Chromosomal translocations in various neoplasms produce protein tyrosine kinase fusion genes, and such

The NUT protein (**C**) (peroxidase DAB) is expressed in tumor cells but not in admixed histiocytes and lymphocytes.

oncogenes are of considerable clinical importance. Protein tyrosine kinases comprise a large family of proteins, which are primarily involved in signal transduction. All tyrosine kinase proteins contain a highly conserved kinase (catalytic) domain, which mediates the phosphorylation of tyrosine residues in protein substrates. Phosphorylated tyrosines serve to stabilize various protein-protein interactions and to enhance kinase activity in those substrates with intrinsic kinase function. Tyrosine kinase fusion oncoproteins resulting from chromosomal translocations in cancer have a consistent structure. The carboxyl-terminal end of these fusion oncoproteins typically contains the entire kinase domain from the tyrosine kinase protein, whereas the amino-terminal end contains an oligomerization domain from the other fusion partner. The oligomerization domain facilitates spontaneous interactions between kinase fusion oncoproteins, and the complexed oncoproteins can then phosphorylate each other, resulting in further upregulation of kinase activity.

The Philadelphia (Ph) chromosome is the cytogenetic hallmark of chronic myelogenous leukemia (CML) and was the first diagnostic translocation identified in a human cancer, also providing the best known example of a fusion tyrosine kinase oncogene.[111] The Ph chromosome results from chromosomal translocation between chromosomes 9 and 22, in which the *BCR* gene on chromosome 22 is fused with the *ABL1 (ABL)* kinase gene on chromosome 9. This translocation is found in most CMLs, 25% of ALLs in adults, 5% of ALLs in children and, less often, in AML. *ABL* encodes a 145-kD nonreceptor protein tyrosine kinase that shuttles between the nucleus and cytoplasm and is involved in various cellular processes, such as cell cycle regulation and apoptosis. *BCR* encodes a 160-kD protein with dimerization, serine-threonine kinase, Rho-GEF (guanine nucleotide exchange factor), and Rac-guanosine triphosphatase (GTPase) domains. The BCR-ABL fusion oncoprotein is expressed as three structural variants, depending on the location of the breakpoint in the *BCR* gene. The BCR-ABL fusion transcript types segregate with specific neoplasms so that the 190-, 210-, and 230-kD BCR-ABL proteins are typically expressed in ALL, CML, and chronic neutrophilic leukemia, respectively. In AML, BCR-ABL fusion oncoproteins can be the P210 or P190 form.[112] The BCR-ABL fusion oncoproteins feature constitutive activation of the ABL kinase domain, resulting in autophosphorylation and tyrosine phosphorylation of various substrates. The phosphotyrosine residues serve as binding sites for various signaling proteins, resulting in activation of signaling pathways, such as Ras/MAPK (implicated in cell proliferation) and PI3K/AKT (implicated in cell survival).

Translocation-associated fusion kinase oncogenes are also found in various soft tissue tumors, including congenital fibrosarcoma, a pediatric spindle cell neoplasm with an excellent prognosis. Cytogenetically, congenital fibrosarcoma is characterized by the balanced translocation t(12;15)(p13;q25), which fuses the 5′ end of the transcription factor gene *TEL* to the 3′ end of the *NTRK3* protein tyrosine kinase gene (see Fig. 45-2).[113] The TEL-NTRK3 fusion oncoprotein retains the TEL helix-loop-helix dimerization domain and the NTRK3 kinase domain. *TEL* is also rearranged with other genes, including protein tyrosine kinase genes in various leukemias. The *TEL-NTRK3* fusion gene is seen in pediatric renal tumors known as congenital cellular mesoblastic nephromas, which are histologically similar to congenital fibrosarcoma (Fig. 45-16).[7] This finding suggests that congenital fibrosarcoma and cellular mesoblastic nephroma belong to the same spectrum of tumors. TEL-NTRK3 is also found occasionally in AML[6] and is one of a few fusion oncogenes known to play transforming roles not only in soft tissue and hematopoietic neoplasms[114] but also in epithelial neoplasia (secretory breast carcinoma).

Inflammatory myofibroblastic tumor (IMT) is an unusual entity that arises predominantly in the abdominal cavity/peritoneum of young patients. Similar to congenital fibrosarcoma, IMT is usually associated with an excellent prognosis and metastases are rare. However, a subset of patients with IMT do develop disseminated disease and it is notable that many IMTs have chromosomal translocations that create activated fusion forms of the *ALK* receptor tyrosine kinase gene detectable by immunohistochemical means (Fig. 45-17).[114] *ALK* oncogenic fusion genes were initially described as a consequence of the chromosomal translocation t(2;5)(p23;q35), which occurs in a subset of anaplastic large cell lymphomas (ALCLs).[115] At least nine *ALK* fusion genes have now been described in IMT and ALCL; in all of them,

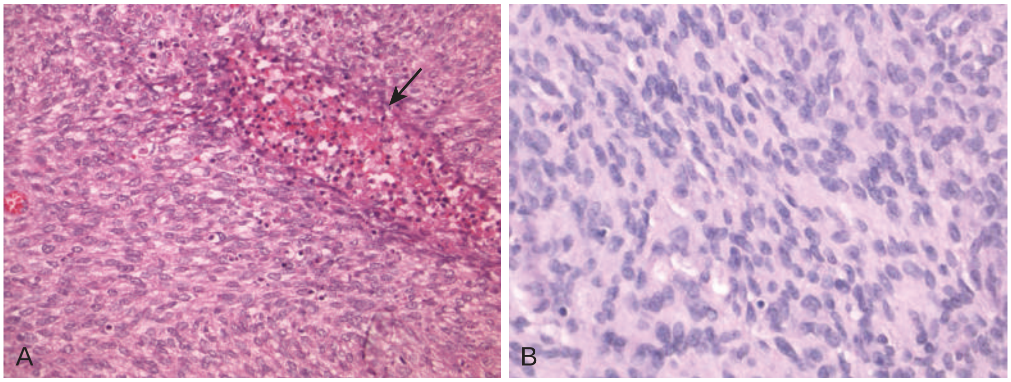

Figure 45-16 **A,** Congenital mesoblastic nephroma and **B,** infantile fibrosarcoma are histologically indistinguishable tumors composed of mitotically active plump spindle cells, with varying extent of fascicular arrangement and showing islands of spontaneous necrosis as a characteristic feature *(arrow)*.

the resultant fusion oncoproteins contain the ALK kinase domain fused to an oligomerization domain of another protein. Two of the *ALK* fusion genes, *TPM3-ALK* and *CLTC-ALK*, have been found in IMT and ALCL, indicating that an identical oncogenic mechanism can contribute to these different tumors.[114,116] Most recently, *ALK* kinase domain mutations and gene amplification have been demonstrated in hereditary and sporadic neuroblastoma.[117,118,119] Other receptor tyrosine kinase translocations in pediatric cancer include those in papillary thyroid cancers, which can target the *RET* or *NTRK1* genes.[120,121] In these fusion oncoproteins, the RET or NTRK1 kinase domains are activated by fusion with various oligomerization-inducing domains.

A further mechanism of protein tyrosine kinase activation by chromosomal translocation is seen in dermatofibrosarcoma protuberans (DFSP).[122] DFSP is a subcutaneous plump spindle cell sarcoma that exhibits high local recurrence rates but rarely metastasizes. Cytogenetically, this tumor is characterized by the chromosomal translocation t(17;22)(q21;q13), often amplified within a circular or ring chromosome (see Fig. 45-13A). The t(17;22) creates a *COL1A1-PDGFB* fusion gene, in which the entire *PDGFB* coding sequence is placed under the transcriptional control of the highly active *COL1A1* promoter in an event referred to as promoter swapping. This mechanism results in *PDGFB* overexpression, with resultant autocrine activation of the PDGFB receptor.[122] The same genetic event underlies the development of giant cell fibroblastoma, which is a pediatric tumor believed to be closely related to DFSP.[74,123]

Chromosomal Rearrangements Associated with Transcriptional Upregulation of Nonfusion Oncogenes

Many pediatric lymphomas feature juxtaposition of intact protooncogenes to transcriptionally active loci (e.g., the *IG* locus in B-cell lymphomas or the *TCR* locus in T-cell lymphomas). V(D)J recombination and class switch recombination, which normally occur within the *IG* or *TCR* loci in lymphocytes, have been implicated in the genesis of these nonfusion genes.[124] V(D)J recombination and class switch recombination mechanisms are exemplified by the nonfusion genes targeting *MYC*, a regulator of cell growth and survival, in many Burkitt lymphomas. V(D)J recombination facilitates the chromosomal translocation t(8;14)(q24;q32) in endemic Burkitt lymphomas found in patients from equatorial Africa. This translocation juxtaposes *MYC* to the intronic *IG* heavy chain gene enhancer, leading to MYC overexpression. In contrast, most nonendemic Burkitt

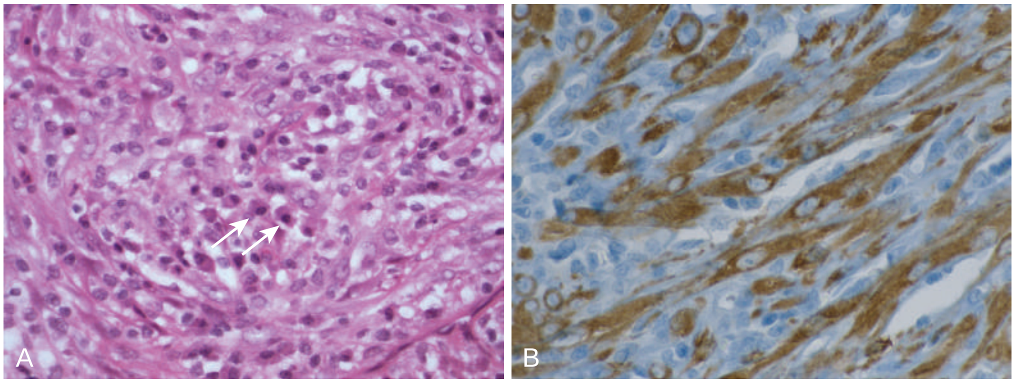

Figure 45-17 **A,** Inflammatory myofibroblastic tumor composed of plump neoplastic spindle cells with a reactive infiltrate featuring abundant plasma cells *(arrows)*. **B,** Immunohistochemistry in a case with *TPM4-ALK* fusion, showing diffuse cytoplasmic staining with nuclear sparing in spindle cell (myofibroblastic) component and absence of immunoreactivity in the inflammatory cell infiltrate.

lymphomas have translocation breakpoints downstream elsewhere in the *IG* heavy chain gene locus, juxtaposing *MYC* to other enhancers. Alternatively, *MYC* overexpression can result from juxtaposition to the *IG* κ or λ light chain genes resulting from t(2;8) or t(8;22).

Like Burkitt lymphomas, follicular cell lymphomas of B-cell origin also feature rearrangements of *IG* loci, but with *BCL2* or *BCL6,* rather than *MYC,* typically overexpressed by translocation into the region of an *IG* gene promoter. *BCL2* alterations, conferring well-described antiapoptotic effects, often result from *IG* heavy chain V(D)J recombination, with a breakpoint in exon 3 of *BCL2* becoming fused to the 5′ end of J_H or D-J_H heavy chain segments. These mechanisms result in *BCL2* transcriptional upregulation, mediated by the *IG* heavy chain gene enhancer. Although deregulated BCL2 expression provides a survival advantage in such lymphomas, additional gene mutations are needed for full neoplastic transformation.[125] However, in the pediatric population, follicular lymphomas are uncommon and the vast majority of cases feature elevated BCL6 expression. Cases with t(14;18) fusing the *IGH* chain locus with the BCL2 gene comprise only a small subset of the cases, which is in contrast to adults, but increased BCL2 expression is associated with advanced disease and a poor prognosis in pediatric lymphoma.[126]

TCR locus rearrangements are demonstrable in many T-cell leukemias and lymphomas, resulting in transcriptional upregulation of various translocated genes, similar to the mechanisms involving *IG* gene regions in various B-cell malignancies. The T-cell leukemia and lymphoma cytogenetic rearrangements dysregulate expression of transcription factor genes, such as *MYC, HOX11, TLX3 (HOX11L2), TAL-SCL, LYL1, LMO1,* and *LMO2,* by placing these genes under the control of highly active *cis*-acting transcriptional regulatory *TCR* elements, although dysregulation of these T-cell oncogenes can also occur in the absence of cytogenetic *TCR* rearrangements.[127,128]

Translocations resulting in nonfusion oncogenes can be found in pediatric solid tumors; one example is the *PDGFB* fusion gene in DFSP (see earlier). Other examples include translocations of chromosome 8, targeting the *PLAG1* gene, a zinc finger transcription factor, in salivary gland pleomorphic adenoma and the primitive adipose tumor lipoblastoma. In both tumor types, the chromosomal breakpoints occur in the 5′ noncoding regions of the involved genes, resulting in promoter swapping, in which the transcriptionally inactive *PLAG1* promoter is replaced by the highly active promoter of the translocation partner gene, leading to *PLAG1* overexpression.[129-131]

BIOLOGIC BASIS FOR SPECIFICITY OF BALANCED CHROMOSOMAL REARRANGEMENTS: DIAGNOSTIC RELEVANCE

Recurrent chromosomal rearrangements involving specific breakpoint regions are increasingly being used as diagnostic markers in various pediatric cancers. Translocations are the most extensively studied of these rearrangements, but other mechanisms include chromosomal insertions, inversions, and interstitial deletions. Although diagnostic rearrangements, such as those involving chromosome 22 in Ewing sarcoma, have become useful biomarkers, it is unclear whether most such characteristic rearrangements are initiating tumorigenic events or later events responsible for tumor progression. However, their oncogenic nature is generally convincing in that they can transform cells, as can be demonstrated by expressing the oncogenes in nonneoplastic cells in vitro or in mice. Although *EWS* and its family member *TLS-FUS* are frequently rearranged in chromosomal translocation in sarcomas, the partner gene varies and appears occasionally to dictate the tumor phenotype (see Table 45-1). For example, *EWS-WT1* transcripts are found in DSRCT but not Ewing sarcoma, whereas *EWS-ATF1* fusion occurs in soft tissue clear cell sarcoma but not other sarcomas. It has not yet been clearly established whether it is the partner gene that determines lineage in these tumors or whether only certain cells, already lineage committed, might tolerate the presence of these oncogenic transcripts.

Translocations of the *MLL* gene at chromosome band 11q23 are examples of leukemia-associated chromosomal translocations that create potent fusion oncoproteins. *MLL* translocations are believed to be the events that initiate these leukemias.[132] Analogous to *EWS* variant rearrangements in pediatric solid tumors, particular *MLL* partner genes are more likely to occur in ALL than in AML, even though there is some overlap, and leukemias with *MLL* translocations can also exhibit dual lineage or actually switch lineage.[133]

There is substantial evidence that single genetic aberrations are insufficient to produce cancer. Rather, tumor development requires many gene mutations, perturbing different aspects of the cell biology (including apoptosis, proliferation, differentiation, and adhesion), which collectively results in the neoplastic phenotype. Even with *MLL* translocations in which there is a short latency from the in utero occurrence of the translocation to manifestation of disease, which is often in the young infant (<3 months old) or even in the neonate or the fetus,[134] there are characteristic secondary alterations in addition to the translocations.[135]

Some of the same characteristic genetic alterations, including chromosomal translocations, observed in human cancers have been detected at very low levels (e.g., 1 in 10,000 cells) in nonneoplastic cell populations.[136,137] The rare cells containing these alterations are individually at low risk for progression to malignancy, presumably because it is unlikely that they will acquire the other mutations required to result in clinically evident cancer. However, this likely is more pertinent to solid tumors, in which a greater number of events generally is believed to be required for full oncogenesis than in leukemias. Similarly, it is likely that various diagnostic genetic alterations can be detected at very low levels in cancer types in which they are not characteristically encountered and where they likely are not serving an important transforming role for the vast majority of cells in that cancer. Therefore when using genetic alterations as diagnostic markers, it is important to have some sense that the alteration is found in most cells in the cancer, rather than being a rare and perhaps trivial event. It is similarly crucial to correlate the genetic findings with the histology, thereby confirming that the molecular diagnosis is credible.

The recurring and relatively specific association of chromosomal translocations with one or a few types of cancer has enabled the development of assays in which the translocations serve as ancillary diagnostic markers. There is a biologic basis to such tumor specificity because the neoplastic phenotype is essentially a symbiotic interaction between cell environment and translocation product, and certain genetic alterations, particularly those resulting from translocations, appear oncogenic in only a limited number of cancer cell environments.[138] Support for this concept is provided by B-cell lymphomas, in which diagnostic translocations often juxtapose oncogenes to the *IG* loci. The *IG* gene promoters are extremely active in the B-cell context, and ectopic placement of oncogenes near these promoters results in striking overexpression of the oncogenes, provided that the chromosomal rearrangement occurs in the B-cell context. By contrast, this same chromosomal rearrangement would presumably be irrelevant in other cell types, in which the *IG* genes are transcriptionally silent. Translocations that occur in B-cell lymphoma have not been found in other varieties of human cancer. Another factor accounting for tumor specificity is the restriction of transforming properties of translocation-associated oncoproteins to certain cell lineages. Fusion oncoproteins always require interactions with other cellular proteins that facilitate and support the effect of that oncoprotein. Therefore cell lineages lacking the relevant interacting proteins will not be transformed by a given fusion oncoprotein. These concepts are underscored by the observation that the BCR-ABL fusion oncoprotein, which is highly transforming in hematopoietic progenitor cells, fails to transform fibroblast cell lines.[139]

In pediatric tumors, genetic aberrations useful for testing as ancillary diagnostic findings are especially frequent in sarcomas, leukemias, and lymphomas. Interestingly, in contrast to adult tumors, diagnostic alterations are also found in many pediatric carcinomas, including papillary and follicular thyroid carcinomas, renal cell carcinomas, and lethal midline carcinoma. Although cytogenetic and molecular profiles are diagnostic in some pediatric cancers, there are many others that lack specific genetic or cytogenetic aberrations or have extremely complex karyotypes in which the specific aberrations, if present at all, are difficult to identify.

CYTOGENETIC AND MOLECULAR PATHOLOGY: MAJOR TUMOR TYPES

Cytogenetic and molecular analyses have provided extraordinary insights into the biology and pathogenesis of pediatric cancer and, in some cases, these insights have then formed the basis for more accurate assessment of diagnosis and prognosis. However, neither cytogenetic nor molecular methods are required routinely in the clinical setting. In some pediatric solid tumors, there is not yet a basis for genetic testing because recurrent genetic aberrations are unknown. In others, particularly those that are benign clinically, the histopathology diagnosis and prognosis are generally straightforward and genetic adjuncts are therefore irrelevant. Some pediatric solid tumors, such as high-grade osteosarcoma, have extremely complex karyotypes, so that to date, there is little clinical advantage in genetic analysis, given the formidable task of describing the many genetic aberrations in a given tumor and the questionable prognostic relevance of the individual genetic perturbations. Widespread application of genetic assays in such tumors awaits the identification of key genetic predictors, which might then be determined in tumor interphase cells by molecular cytogenetic assays.

The following sections will highlight applications of cytogenetic and molecular assays in subsets of pediatric tumors, in which the technical challenges of genetic assays are manageable, and in which genetic findings are acknowledged to provide important diagnostic or prognostic information.

Mesenchymal Neoplasms: Soft Tissue and Bone Tumors

Ewing Sarcoma

Ewing sarcomas are highly aggressive tumors, characteristically occurring in bone and soft tissue, but also, less commonly, in viscera, and in which the neoplastic cells are generally of the small, round, blue cell type. Ewing sarcoma and peripheral primitive neuroectodermal tumor (pPNET), although historically considered distinct entities, share molecular and morphologic features and are now regarded as essentially the same entity (herein referred to simply as Ewing sarcoma). Ewing sarcomas typically contain chromosomal translocations involving the Ewing sarcoma gene (*EWS* or *EWSR1*), which is located on the long arm of chromosome 22. These translocations involve a number of partner genes (see Table 45-1), with the most common translocation being t(11;22)(q24;q12), resulting in oncogenic fusion of 3′ sequences of the *FLI1* gene on chromosome 11 with 5′ sequences of *EWS*.[140-144] *FLI1* belongs to the winged helix-loop-helix transcription factor family that share a conserved 85-amino acid ETS domain that is present in all EWS-ETS fusions. The oncogenic *EWSR1-FLI1* fusion gene encodes an activated version of transcription factor in which the DNA binding domain of *FLI1* is fused to the more potent *trans*-activating domain (TAD) of *EWSR1*, replacing the TAD of *FLI1*. In variant translocations, *EWS* is fused with alternative ETS transcription factor family members (see Fig. 45-10 and Table 45-1)[145-149] and, rarely, the *EWS*-related gene, *FUS*, can also be fused with an alternative ETS family member in Ewing sarcomas (Fig. 45-18; see Table 45-1).[150] The *EWS* family and ETS family gene translocations are apparently essential for oncogenesis, being found in almost all Ewing sarcomas.

These translocations are readily detected by conventional cytogenetic methods, even using needle biopsy material, because Ewing sarcoma cells grow well in tissue culture.[9] The translocations can also be detected by FISH,

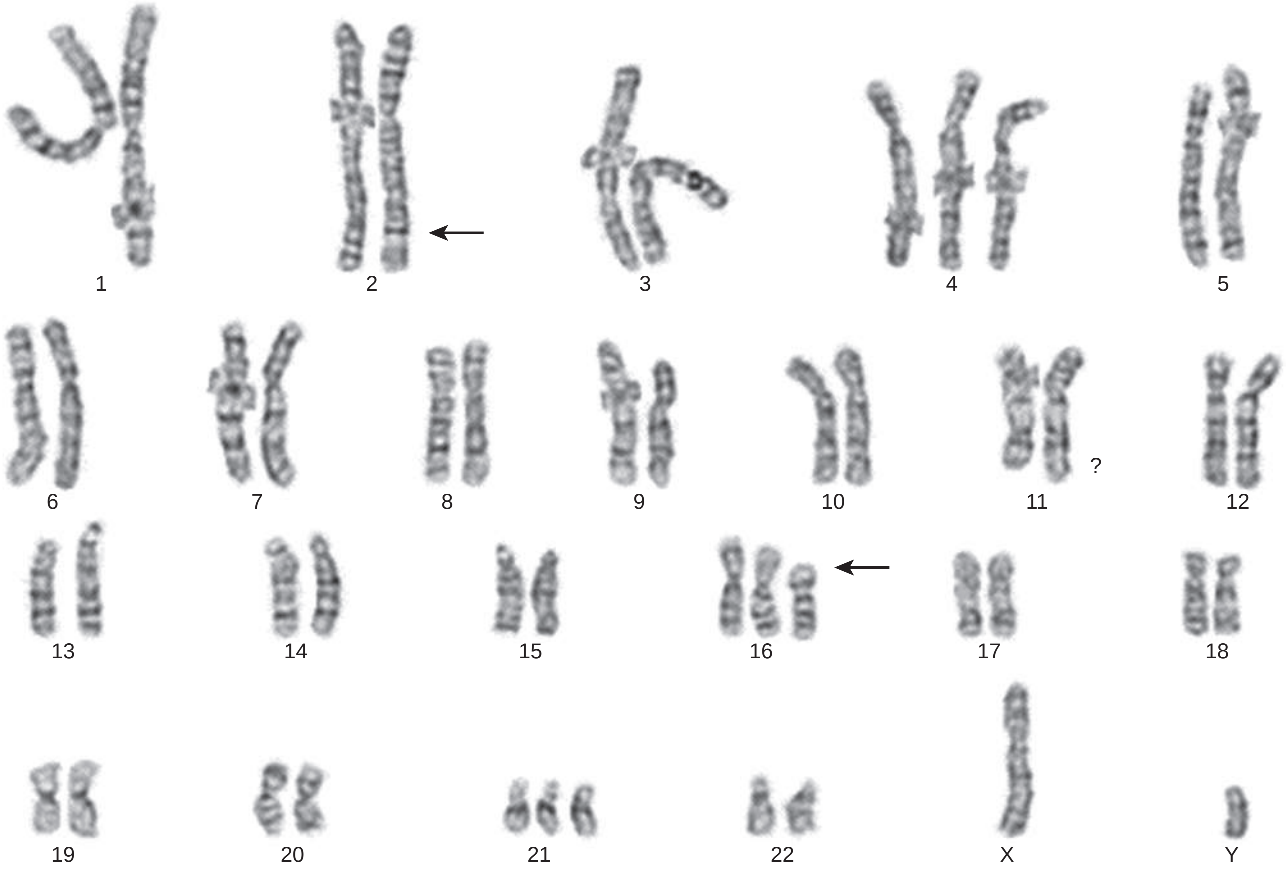

Figure 45-18 Ewing sarcoma with t(2;16)(q35;p11), resulting in oncogenic fusion of the *FEV1* and *FUS* genes (*arrows* indicate translocation breakpoints).

typically using dual-color probes flanking the *EWSR1* locus (see Fig. 45-8).[151] Although this does not identify the partner gene fused to *EWSR1*, that information is generally unnecessary for diagnostic purposes. Another method for detecting these translocations is RT-PCR.[152] Advantages of PCR include superior sensitivity, identification of the *EWS* fusion partner gene, and identification of the breakpoint locations within the genes. The most common fusion is between *EWS* exon 7 and *FLI1* exon 6, known as type I fusion, whereas type II fusion involves fusion of *EWSR1* exon 7 with *FLI1* exon 5, and many further variants have been described (see Fig. 45-10). Although several studies have indicated that *EWSR1-FLI1* breakpoint locations might be prognostic in Ewing sarcoma,[37,39,153] with tumors bearing the type I transcript doing better than all others, more recent studies do not confirm this, and such information is not used routinely to guide therapeutic decisions.

Although histomorphologic and immunohistochemical features are often sufficient to establish the diagnosis of Ewing sarcoma, genetic corroboration of the diagnosis is highly reassuring in distinguishing Ewing sarcoma from other small round blue cell tumors, particularly in situations in which tumor arises at an unusual site, or outside the typical age range, in the context of smaller biopsies, or if tumor cell preservation is compromised and/or immunohistochemistry is suboptimal. Although the cells are essentially undifferentiated, and superficially similar or identical to those in many other small round cell tumors, there are nonetheless characteristic findings, such as subtle cytologic features and crisp cytoplasmic membrane–associated expression of the CD99 (O13-HBA71, pseudoautosomal gene-encoded membrane glycoprotein [Fig. 45-19], or specifically for *Erg*-rearranged Ewing sarcoma, anti-Erg monoclonal antibody[154]) that aid the diagnosis.

Thus the combined traditional histologic evaluation of H&E-stained sections, together with immunohistochemical profiling, enables distinction of Ewing sarcoma from, for example, a reasonable mimic in alveolar rhabdomyosarcoma by the demonstration of CD99 expression in Ewing sarcoma versus expression of myogenic markers such as myogenin, MyoD1, and desmin in rhabdomyosarcoma (Fig. 45-20). The characteristic oncogene fusions in Ewing sarcoma *(EWS-FLI1)* and alveolar rhabdomyosarcoma *(PAX-FOXO1)* might contribute to the distinct cell differentiation profiles that separate these two round cell tumors immunophenotypically and morphologically. Evidence to this effect has been obtained from in vitro studies in which *EWS-ETS* oncogenes can induce neuroectodermal differentiation,[155] whereas *PAX-FOXO1* induces a myogenic program.[156,157] Secondary

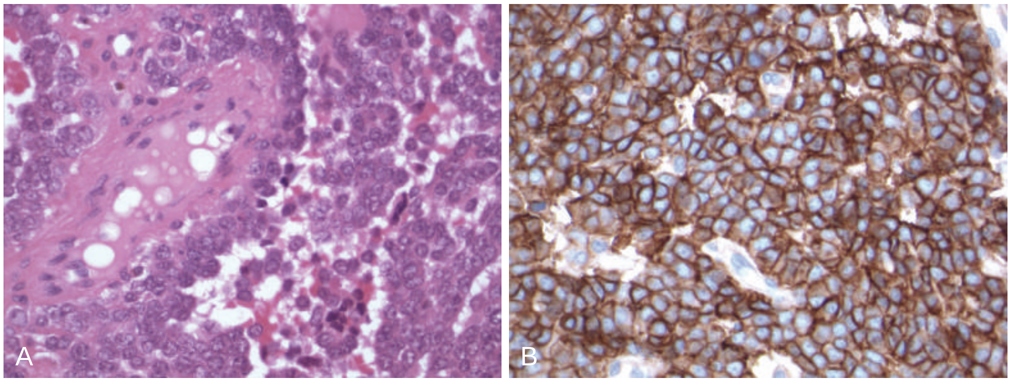

Figure 45-19 Ewing sarcoma composed of undifferentiated round cells (**A**) arranged around thick fibrovascular cores and demonstrating strong and crisp CD99 expression confined to the cell surface (**B**), producing a mosaic-like effect.

genetic aberrations in Ewing sarcoma include *TP53* mutation and *CDKN2A* deletion, which are each found in approximately 25% of cases and are more frequent in cases that are clinically aggressive and poorly chemoresponsive.[158]

Similarly, gain of 1q was strongly associated with relapse and poor outcome, and this is apparently due to overexpression of *DTL (CDT2)*, a ubiquitin ligase gene located on chromosome 1q.[159,160] Independent loss of 16q was also predictive of worse overall and event-free survival regardless of stage at presentation.[159] In that study, gain of chromosome 12 was, at least in cases of localized disease at presentation, associated with worse event-free survival whereas deletion of 6p has been associated with worse outcome also.[161] Genomic instability portends poorly insofar as tumors with more than three copy number alterations reportedly did worse than those with three of fewer.[162,163] However, currently these secondary genomic findings are not used in therapeutic decisions.

Rhabdomyosarcoma

Rhabdomyosarcomas are malignant tumors featuring skeletal muscle differentiation, with several histologic subtypes (see Fig. 45-20). The major varieties in

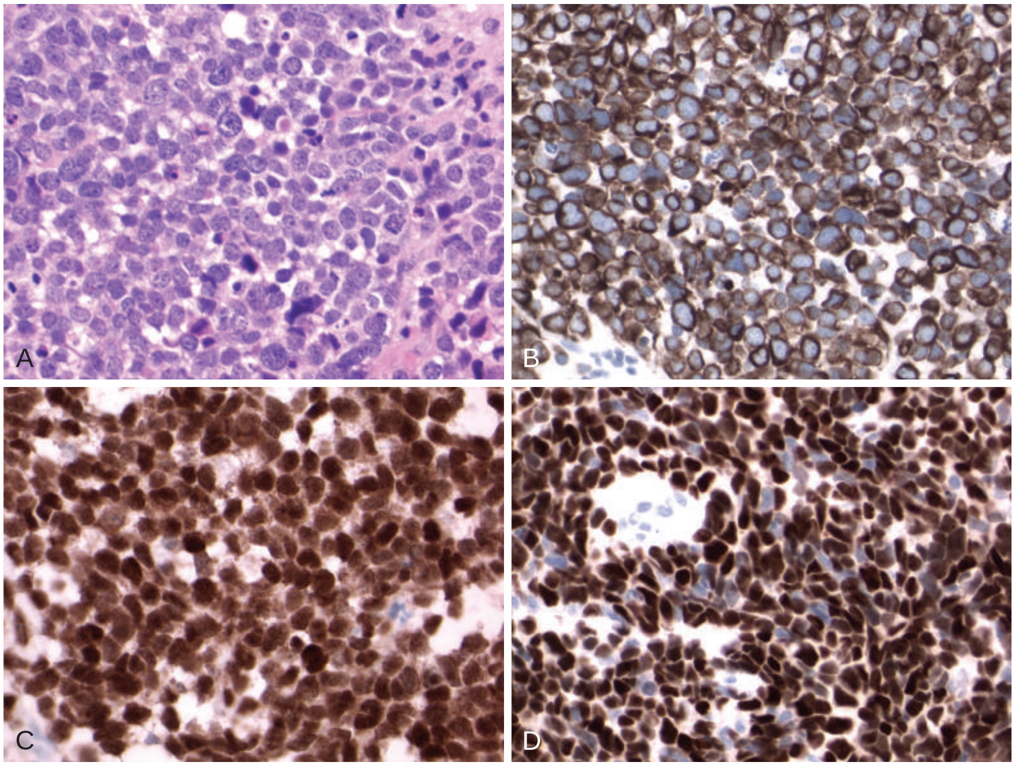

Figure 45-20 Solid variant of alveolar rhabdomyosarcoma composed of undifferentiated, moderately pleomorphic round cells histologically (**A**), but with convincing evidence of myogenic differentiation, as demonstrated by strong and diffuse cytoplasmic expression of desmin (**B**) and nuclear reactivity for MyoD1 (**C**) and myogenin (**D**). Of note, the percentage of nuclei reacting for both myogenin and MyoD1 is very high, as is typical of the alveolar variant of rhabdomyosarcoma.

childhood are the embryonal and alveolar subtypes and, although there are classic morphologies of alveolar and embryonal rhabdomyosarcoma, the distinction is not always clear-cut, because a solid variant alveolar rhabdomyosarcoma exists and composite cases also occur. Therefore especially with decreasing biopsy size, traditional morphologic distinction between embryonal and alveolar subtypes of rhabdomyosarcoma is not always a reliable means of subclassifying the tumors but is nonetheless essential for appropriate therapeutic stratification of patients with these two biologically different tumors. Alveolar rhabdomyosarcoma exhibits a higher proportional nuclear reactivity for both myogenin and MyoD1 than embryonal rhabdomyosarcoma,[164] but even this feature may be unconvincing in small biopsies and thus be of little value in firmly establishing the diagnosis. The biologically distinct nature of embryonal and alveolar subtypes is confirmed by genetic studies, which show translocations targeting the chromosome 13 *FOXO1A* (forkhead transcription factor) gene in most alveolar rhabdomyosarcomas, and nontranslocation cytogenetic alterations, including 11p deletion, trisomy 8, and trisomy 20, in embryonal rhabdomyosarcomas. In 70% to 80% of alveolar rhabdomyosarcomas there is fusion of the *FOXO1* gene with the *PAX3* gene on chromosome 2,[165-167] and approximately 10% have fusions of *FOXO1* with the *PAX7* gene on chromosome 1.[168] The *PAX7-FOXO1* fusion is often highly amplified in the form of double-minute chromosomes (see Fig. 45-13B), whereas the *PAX3-FOXO1* fusions are not usually amplified. This difference appears to reflect the lower intrinsic expression of *PAX7-FOXO1,* relative to that of *PAX3-FOXO1,* with genomic amplification therefore required to provide a comparable and sufficient level of oncogenic transcript.[169] The *FOXO1, PAX3,* and *PAX7* genes encode transcription factors, and the *PAX3-FOXO1* and *PAX7-FOXO1* fusion oncogenes encode activated forms of those transcription factors[170,171] that function to induce myogenic differentiation programs.[156,157,172] Notably, alveolar rhabdomyosarcomas with *PAX7-FOXO1* rearrangements were reported in one study to have better prognoses than those with *PAX3-FOXO1* when comparing patients presenting with metastatic disease.[173] Furthermore, an argument has been made for movement toward designation of rhabdomyosarcomas based on translocation status rather than on morphology; and in that vein, cases of morphologic alveolar rhabdomyosarcoma have been termed *fusion-positive* versus *fusion-negative*. The observation that gene expression profiles of fusion-negative alveolar rhabdomyosarcomas are indistinguishable from those of embryonal rhabdomyosarcomas[174-177] might lend considerable support to such subclassification. Whether molecular categorization however translates well to clinical prognosis and treatment stratification remains unresolved,[176,178,179] and a combined morphomolecular diagnosis is currently considered best practice.[180]

A proportion of cases of rhabdomyosarcoma lacking the canonical *PAX-FOXO1* fusions show t(2;2)(p23;q35) or t(2;8)(q35;q13) in which *PAX3* is fused with either *NCOA1* or *NCOA2,* which are nuclear receptor transcriptional coactivators,[181] whereas isolated individual cases of rhabdomyosarcoma were reported to show t(2;6)(p23;p21.1),[182] t(4;22)(q35;q12) fusing *EWSR1* with *DUX4,*[183] and a complex t(8;13;9)(p11.2;q14;q32) apparently resulting in amplification of *FGFR1-FOXO1* fusion.[184]

Synovial Sarcoma

Synovial sarcomas may be monophasic (Fig. 45-21), in which the tumor is predominantly composed of spindle cells, or biphasic, in which the tumor contains both spindle cell and epithelioid elements, with the latter exhibiting more convincing epithelial immunophenotypic characteristics or, uncommonly, poorly differentiated, with a primitive round cell morphology reminiscent of Ewing sarcoma. Apart from the epithelial markers epithelial membrane antigen (EMA) and cytokeratins, transducer-like enhancer protein 1 (TLE1) also has been validated from gene expression profiles as a reliable marker for synovial sarcoma.[185-187] Synovial sarcomas feature translocation of chromosomes X and 18, t(X;18)(p11;q11).[188,189] t(X;18) is found in more than 90% of synovial sarcomas but not generally in histologic mimics such as hemangiopericytoma, mesothelioma, leiomyosarcoma, or malignant peripheral nerve sheath tumor. The molecular underpinnings of t(X;18) are complex in that the oncogene on chromosome 18 (*SYT* or *SS18*) can be

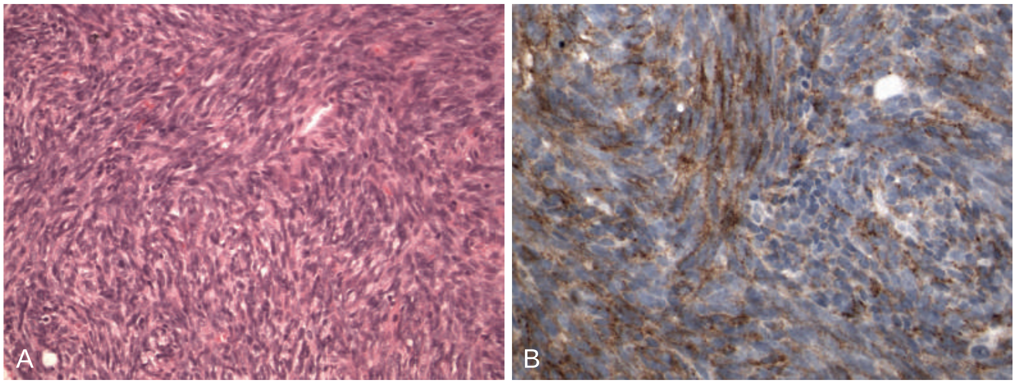

Figure 45-21 **A,** Monophasic synovial sarcoma, with interdigitating fascicular arrangement of fusiform spindle cells. **B,** Weak, patchy immunohistochemical staining for epithelial membrane antigen (EMA) in the spindle cells.

fused with one of several almost identical genes (generally *SSX1* or *SSX2* and, rarely, *SSX4*) on chromosome X.[190,191] *SSX1* and *SSX2* are adjacent genes and, given their close proximity, it is impossible to distinguish *SS18-SSX1* and *SS18-SSX2* translocations using conventional chromosomal banding methods. However, the alternative *SSX* fusions can be demonstrated by FISH or RT-PCR using specific probes or primers, respectively.[192,193] One study has suggested that synovial sarcomas with the *SS18-SSX1* fusion are typically biphasic, whereas those with *SS18-SSX2* can be biphasic or monophasic and have better metastasis-free survival compared with those bearing *SS18-SSX1* fusions.[194] This morphologic-genotypic correlate is substantiated by studies of SS18-SSX1 and SS18-SSX2 interactions with SNAIL and SLUG, both transcriptional repressors of E-cadherin, which mediates mesenchymal to epithelial transition.[195]

The SS18-SYT fusion protein is both necessary and sufficient for cellular transformation.[196] SS18 and SSX contribute, respectively, transcriptional coactivator and repressor domains to the SS18-SSX fusion proteins, and, despite the lack of any DNA binding domain, exert an effect on gene transcriptional dysregulation apparently through association with chromatin remodeling proteins Trithorax (TRX) and the Polycomb repressor complex (PRC2).[197-200] Mass spectrometry has revealed that SS18-SSX fusion proteins bind TLE1 and ATF2 to form a complex necessary for tumor cell survival. ATF2 is the DNA binding partner of SS18-SSX, and the epigenetic repression of ATF2 is dependent on TLE1, the recruitment of which can be abrogated by HDAC inhibitors, which have already shown considerable promise in preclinical trials.[201] In addition, SS18-SSX competes physically with wild-type SS18, forming an altered complex lacking SMARCB1. This altered complex transactivates *SOX2*, which is a diagnostic marker that is universally overexpressed in synovial sarcoma and essential for synovial sarcoma proliferation.[202]

Adipose Tumors

Most subtypes of adipose tumors, whether benign or malignant, contain distinctive genetic aberrations (see Table 45-1). Useful diagnostic markers include 8q rearrangement in lipoblastoma, 12q rearrangement in lipoma, ring chromosomes in well-differentiated and dedifferentiated liposarcoma, and t(12;16) in myxoid or round cell liposarcoma.

Lipoblastomas are pediatric adipose tumors containing variable numbers of primitive cells (lipoblasts) and generally bearing translocations of the chromosome 8 long arm at bands 8q11-12, resulting in rearrangement of the *PLAG1* zinc finger oncogene.[130] Reports of individual cases each of lipoblastoma[203] and lipoma[204] bearing translocations involving 8q21.1 region in each case as well as with a t(9;12)(p22;q14) in a pediatric intramuscular lipoma[205] add to the variability in observations in these benign fatty neoplasms. Hibernomas, which contain adipose cells with a brown fat phenotype, generally have rearrangements of the chromosome 11 long arm,[206] although the gene target of that translocation has not been identified.

Another diagnostically useful aberration is the translocation of chromosomes 12 and 16 found in myxoid liposarcomas.[207-209] This translocation is also found in round cell liposarcomas and is retained in myxoid liposarcomas that acquire round cell features and thereby undergo transition to higher histologic grade.[210,211] t(12;16) results in fusion of the *DDIT3 (CHOP)* transcription factor gene on chromosome 12 to the *TLS* gene on chromosome 16,[212,213] and the resultant fusion oncoprotein is an activated transcription factor. t(12;16) has not been found in other subtypes of liposarcoma or in other types of myxoid soft tissue tumors.[214,215] It appears to be relevant therapeutically, in that patients with myxoid or round cell liposarcoma show impressive responses to trabectedin chemotherapy.[216] However, liposarcoma is rare in childhood and virtually unheard of in the first decade of life.

Clear Cell Sarcoma: Malignant Melanoma of Soft Parts

Clear cell sarcomas of the soft tissues resemble cutaneous melanomas histologically, and therefore have been referred to as melanoma of soft parts. Immunohistochemically, the tumors are consistently positive for S-100 protein, usually at least focally for HMB45, microphthalmia transcription factor (MITF), and Melan A.[217] Despite their histologic and immunohistochemical overlaps, clear cell sarcoma and true melanoma are different clinically. Whereas most melanomas are of cutaneous origin, clear cell sarcomas generally present as isolated masses in deep soft tissues, without apparent origin from, or involvement of, skin. Less commonly they arise in the gastrointestinal tract. Most clear cell sarcomas contain a chromosomal translocation, t(12;22)(q13;q12), while those arising in the gastrointestinal tract will more commonly bear the variant t(2;22)(q34;q12).[218] The latter has, however, also been described in a minor subset of soft tissue–based clear cell sarcoma.[154,219] These translocations have never been reported in cutaneous melanoma and therefore serve as a reliable markers in distinguishing these two tumor types (Fig. 45-22). t(12;22) fuses the *ATF1* gene on chromosome 12 with the *EWS* gene on chromosome 22.[219,220] *ATF1* encodes a transcription factor, and the biologic implications of the translocation are probably similar to those in Ewing sarcoma translocations (see earlier). t(2;22) fuses the *CREB1* gene on chromosome 2, a *CREB* gene family member closely related to *ATF1,* with the *EWSR1* gene.

Desmoplastic Small Round Cell Tumor

DRSCTs are aggressive and chemotherapy-resistant neoplasms that arise most commonly from the peritoneum or intraabdominal soft tissues, particularly in adolescent males.[221] They are composed of undifferentiated malignant small round cells in a striking desmoplastic reaction, ensnaring sharply demarcated islands of tumor cells (Fig. 45-23).[222] Almost all cases express an *EWSR1-WT1* fusion oncogene[222,223] resulting from translocation between the chromosome 11 short arm and chromosome 22 long arm.[224,225] The EWS-WT1 oncoproteins are expressed as several isoforms (see Fig. 45-10), each of which is composed of the EWSR1 amino-terminal

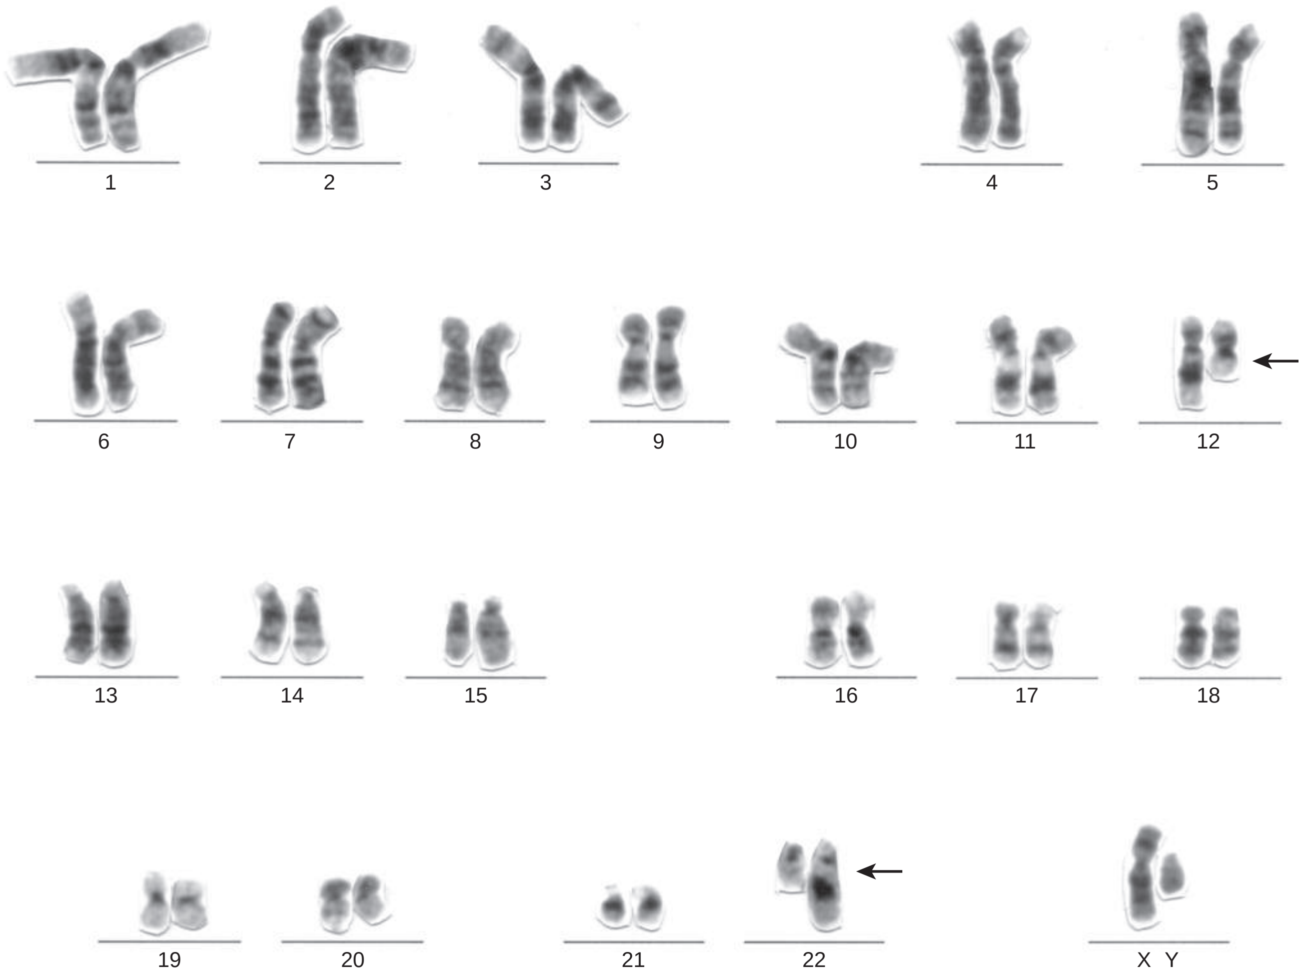

Figure 45-22 Clear cell sarcoma karyotype showing balanced translocation, t(12;22), as the only cytogenetic aberration. *Arrows* indicate translocation breakpoints.

transactivation region fused to the last three of four zinc fingers at the WT1 carboxyl-terminal end.[226,227] These oncoproteins result from fusion of *EWSR1* exon 7, 8, or 9 to *WT1* exon 8. The *EWSR1-WT1* fusion typically results in expression of the carboxyl-terminal but not amino-terminal aspect of WT1 in DSRCT, which may be detected by immunohistochemistry using appropriate antibodies (see Fig. 45-23). Quantitatively minor secondary transcripts lacking exon 6 of *EWSR1* and/or exon 9 of *WT1* are also expressed, although the functional relevance of these transcripts is unknown.[226] However, it is worth noting that the usual immunostaining pattern was not observed in an isolated reported case with atypical transcript that lacked *WT1* exons 9 and 10.[228] The EWSR1-WT1 oncoprotein retains an alternative splicing site (±KTS) between the third and fourth WT1 zinc fingers (see Fig. 45-10). The KTS− isoform regulates genes that are believed to have important biologic roles in DSRCTs, including platelet-derived growth factor-α (PDGFA) and insulin-like growth factor receptor I, whereas the KTS+ isoform regulates a different set of genes.[229] Notably, only the KTS− isoform has shown transforming activity when evaluated in vitro.[230] PDGFA is known to activate potent receptor (platelet-derived growth factor receptor [PDGFR])-mediated mitogenic signaling pathways in fibroblasts,[231] and EWSR1-WT1 might therefore induce desmoplastic proliferation via PDGFA transcriptional upregulation.[227]

Dermatofibrosarcoma Protuberans

DFSP is a low-grade spindle cell tumor, which can occasionally progress to a more aggressive fibrosarcomatous phase. Most DFSPs contain ring chromosomes composed of sequences from chromosomes 17 and 22 (see Fig. 45-13A).[232,233] The ring chromosomes contain multiple copies of a fusion gene, *COL1A1-PDGFB*, in which *COL1A1* (a collagen gene) is contributed from chromosome 17 and *PDGFB* (platelet-derived growth factor-β gene) from chromosome 22.[75,122] Alternatively, DFSP, particularly in pediatric patients, occasionally has t(17;22) translocations, resulting in a single copy of the *COL1A1-PDGFB* fusion gene.[234] The *COL1A1-PDGFB* oncogene

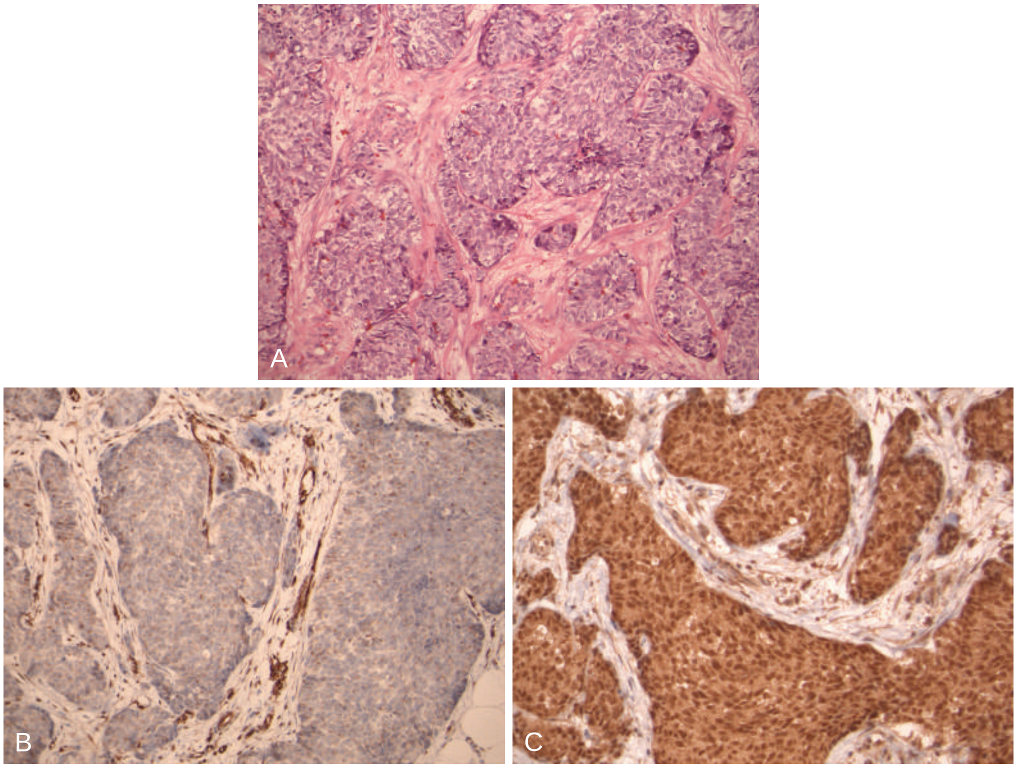

Figure 45-23 **A,** Desmoplastic small round cell tumor with sharply demarcated islands of blue tumor cells separated by pink densely fibrotic "desmoplastic" stroma. Immunoreactivities with antibodies to N-terminal (**B**) and C-terminal (**C**) regions of WT1 are negative and strongly positive, respectively, in the tumor cells, in keeping with EWS-WT1 fusion oncoprotein expression.

results in overexpression of PDGFB, which is a growth factor that activates platelet-derived growth factor receptor-β (PDGFRB) and PDGFRA. This cytogenetic observation has suggested that patients with inoperable DFSP might benefit from treatment with PDGFR inhibitors such as imatinib, and this hypothesis has been confirmed by impressive clinical responses to PDGFRB therapeutic inhibition with imatinib.[235,236,237,238] *COL1A1-PDGFB* oncogenic fusion is also seen in giant cell fibroblastoma (GCF), a pediatric neoplasm closely related to DFSP.[123,239] Studies of GCF and composite GCF/DFSP cases have shown the presence of a single translocation t(17;22) and the resultant *COL1A1-PDGFB* fusion, in the GCF component, with acquisition of additional copies of the oncogene being associated with progression to DFSP.[74]

Desmoid Tumors

Desmoid tumors, also known as deep fibromatoses, contain various genetic aberrations, including the *APC* (adenomatous polyposis coli) gene or *CTNNB1* mutations,[240,241] and trisomies for chromosomes 8 or 20.[242] Cytogenetic deletions of the chromosome 5 long arm are seen in occasional desmoids, resulting in loss of the *APC* tumor suppressor gene.[243,244] However, the most common mutations, particularly in nonfamilial desmoid tumors, are activating *CTNNB1* mutations, which are found in at least 50% of cases.[240,241] Both *APC* inactivating and β-catenin activating mutations result in stabilization and resultant overexpression, of the β-catenin protein with roles in cell proliferation, motility, and differentiation. This overexpression of β-catenin can be detected immunohistochemically in a nuclear distribution.[245] In a retrospective analysis of primary desmoid tumor, the precise β-catenin mutation type was strongly predictive of recurrence, with S45F being associated in multivariate analysis with decreased time to recurrence and overall percentage recurrence.[246] The cytogenetic aberrations in most desmoid tumors, particularly the trisomies 8 and 20, are mechanisms of progression and are acquired subsequent to the *APC* or *CTNNB1* mutations. Interestingly, an as yet unexplained association of desmoidal fibromatosis in patients with gastrointestinal stromal tumor (GIST) has been reported.[247]

Infantile Fibrosarcoma

Infantile (also congenital/infantile) fibrosarcomas characteristically present within the first year of life. These are tumors composed of plump fibroblast-like cells (see Fig. 45-16), which often show high mitotic activity, and feature trisomies of chromosomes 8, 11, 17, and 20.[248] This same group of trisomies occur in the histologically identical pediatric renal tumor, congenital cellular mesoblastic nephroma (see Fig. 45-18).[249] Most infantile fibrosarcomas and congenital cellular mesoblastic nephromas also contain a diagnostic chromosomal translocation, t(12;15)(p13;q26), which is cryptic when studied by traditional cytogenetic banding methods (see Fig. 45-2).[7,113,250] A complex three-way t(12;15;19) translocation has also been reported in infantile fibrosarcoma.[251] t(12;15) (p13;q26) results in fusion of the *TEL* gene on chromosome 12 to the *NTRK3* receptor tyrosine kinase gene on chromosome 15, producing constitutive tyrosine kinase activation. Although challenging to detect by banding methods, the t(12;15) translocation is demonstrated readily by FISH with a dual-color break-apart TEL probe (see Fig. 45-2) or RT-PCR assay.[7,113,250]

Inflammatory Myofibroblastic Tumor

Inflammatory myofibroblastic tumors, belonging to the group of inflammatory pseudotumors, are relatively rare tumors occurring primarily in children and young adults. They are composed of myofibroblastic cells admixed with an infiltrate of lymphocytes and plasma cells (see Fig. 45-17). The inflammatory component of these tumors is nonneoplastic and therefore lacks cytogenetic aberrations, whereas the myofibroblastic cells often contain clonal chromosomal aberrations[252-254] involving rearrangement and oncogenic activation of the *ALK* receptor tyrosine kinase gene at chromosome band 2p23.[114] The *ALK* oncogenes cause constitutive activation of the ALK kinase by enhanced oligomerization resulting from fusion of the ALK kinase domain to the oligomerization domain of the partner gene.[114] *ALK* oncogenic activation is associated with strong, immunohistochemically detectable ALK expression in the inflammatory myofibroblastic tumor spindle cells in about 50% of cases (see Fig. 45-17).[114] The ALK immunohistochemical staining pattern reflects the fusion type, insofar as fusion of ALK with most of the various partners (TPM3, TPM4, CARS, CLTC, SEC31A (SEC31L1),[255] PPFIBP1,[256] ALO17) produces cytoplasmic staining, whereas ALK-RANBP2 fusion produces nuclear membrane–associated reactivity.[257,258] These immunohistochemical findings can distinguish inflammatory myofibroblastic tumor from its histologic mimics, but, given the considerable rate of nonimmunoreactivity, demonstration of *ALK* rearrangement is especially helpful in confirming the diagnosis. An aggressive form of IMT characterized by round cell or epithelioid morphology is described that typically arises intraabdominally in male patients and shows in virtually all cases ALK immunoreactivity in a nuclear, or less commonly, cytoplasmic and perinuclear distribution.[259]

ALK-rearranged inflammatory myofibroblastic tumors are effectively treated with ALK inhibitor crizotinib; however, the emergence of secondary resistance can limit efficacy.[260,261]

Gastrointestinal Stromal Tumor

Most adult GISTs contain activating mutations of the *KIT* or *PDGFRA* oncogenes[262-264] or rarely *BRAF*.[265] These mutations have been targeted with considerable success using the KIT and PDGFRA inhibitor imatinib (Gleevec)[266,267] and second-line tyrosine kinase inhibitors in the context of resistant disease.[268] In addition, germline (inherited) *KIT* mutations are responsible for rare syndromes of familial, multifocal GISTs.[269] However, because most pediatric GISTs do not contain *KIT* or *PDGFRA* mutations they have been termed *wild-type GISTs,* and these predominate as gastric tumors in prepubescent girls.[270-272] In keeping with this, children with metastatic GISTs show only very limited benefit from the KIT-PDGFRA kinase inhibitor therapies. Moreover, pediatric GISTs lack the typical sequential cytogenetic deletions that seem to drive genetic and clinical progression in adult GISTs.[273] Largely through an appreciation of the occurrence of GIST as a component of Carney-Stratakis syndrome/dyad, which is the dominantly inherited predisposition to paraganglioma and GIST,[274,275] underpinned by germline inactivation of subunits B, C or D of succinate dehydrogenase (SDH), it has become evident that deficiency in cellular respiration in fact appears to provide the pathologic basis to all pediatric/wild-type GISTs, despite the low incidence of SDH mutation in such tumors.[276] Germline *SDHA* mutations have been described in isolated cases of paraganglioma and adult wild-type GIST.[277,278] Inactivation of any of the four subunits A, B, C, or D of SDH leads to enzyme complex destabilization and inactivation. Immunohistochemical staining for the B subunit of succinate dehydrogenase (SDHB) provides a surrogate marker for SDH function and is characteristically negative in all pediatric/wild-type GISTs. On this basis, a proposal has been made that GISTs no longer be classed as "mutant" and "wild-type" based on receptor tyrosine kinase mutation but rather be designated type 1 and type 2 as SDHB-positive and SDHB-negative, respectively.[279] Although a strong association with neurofibromatosis type 1 (NF1) exists, in this particular context GISTs usually arise only in adulthood.[280]

Malignant Peripheral Nerve Sheath Tumors

Benign peripheral nerve sheath tumors and malignant peripheral nerve sheath tumors (MPNSTs) are frequent complications in patients with hereditary neurofibromatosis syndromes. These syndromes are the most common tumor predisposition syndromes, affecting 1 in 3500 individuals worldwide. Neurofibromas and malignant peripheral nerve sheath tumors are common in those NF1, whereas benign schwannomas are common in neurofibromatosis type 2 (NF2, central neurofibromatosis). Characterization of the neurofibromatosis syndrome genes has shed substantial light on the pathogenesis of peripheral nerve sheath tumors. The *NF1* and *NF2* genes are located on chromosomes 17 and 22, respectively, and both these genes encode tumor suppressor proteins that normally constrain cellular proliferation.[281-286] NF1 protein tumor suppressor mechanisms involve regulation of RAS GTPase activity,[282,283] with *NF1* gene deletion therefore resulting in constitutive RAS activation, suggesting that therapeutics targeting RAS (or downstream signaling intermediates such as RAF and MEK-MAPK) might be useful for clinical management of MPNSTs and other NF1-associated cancers.[287] MPNSTs often have *NF1* gene deletions, which can be demonstrated by FISH assay. The *NF1* gene aberrations are accompanied by a generally complex karyotype, suggesting that genetic instability plays a prominent role in the development of MPNSTs. Notably, *NF1* gene deletions can be shown in only the Schwann cell component of neurofibromas.[288] This observation supports the view that neurofibromas are clonal Schwann cell neoplasms, whereas the other admixed cell lineages—including fibroblasts, mast cells, and perineural cells—are reactive.

Recent studies demonstrated that the evolution of benign peripheral nerve sheath tumors to MPNST is accompanied predominantly by *loss* of expression of a large number of genes, including, in a vast majority of cases, inactivation of TP53[289] with associated downregulation of the pro-apoptotic miR-34a. MiR-10b, which specifically targets NF1, is upregulated in NF1-associated MPNSTs.[290] Homozygous loss of CDKN2A is also associated with malignant transformation,[291,292] whereas high-resolution copy number profiling has shown, among others, recurrent gains of *PDGFRA, MET, HGF, TP73, EGFR, TERT, MYC,* and *IGF1R* and losses of *NF1, p16^{INK4A}/CDKN2A, RB1,* and *TP53,*[293,294] providing potential basis for novel therapeutic agents[294,295] in this therapeutically challenging sarcoma.

Neuroblastoma

Most neuroblastomas have distinctive cytogenetic features that correlate with their clinical behavior. Favorable prognosis neuroblastomas, which respond well to chemotherapy and can even undergo spontaneous regression, generally feature near-triploid karyotypes without 1p deletion or *MYCN* amplification.[296] Unfavorable prognosis neuroblastomas (Fig. 45-24), by contrast, feature near-diploid or near-tetraploid karyotypes, often accompanied by 1p deletion, 17q amplification, and/or *MYCN* amplification,[297] whereas deletions of 3p and 11q are reportedly predictive of metastasis.[298] In essence, gains of whole chromosomes are more typical of low- or intermediate-risk neuroblastoma whereas segmental chromosomal aberrations are more commonly seen in high-risk cases. *MYCN* amplification, typically manifested as double-minute chromosomes (see Figs. 45-5 and 45-6), is arguably the most ominous of the adverse genetic markers. *MYCN*-amplified neuroblastomas are rarely curable, although complete remission can be achieved through intensive myeloablative chemotherapy. Therefore genetic parameters can be useful adjuncts for determining appropriate intensity of therapy, particularly for those children whose prognoses are not clear based on clinical parameters alone.[297] Cytogenetic analysis of neuroblastoma has been difficult, however, because the tumor cells from most favorable prognosis neuroblastomas fail to divide in culture.[297] *MYCN* amplification and chromosome 1p or 11q deletion and 17q gain can be demonstrated in interphase cells by FISH or CISH (see Fig. 45-6), obviating the need for tumor cell culture.[299,300] It remains unclear whether one or more conventional tumor suppressor genes are targeted by the 1p deletions found in most poor-prognosis neuroblastomas. However, several microRNAs in the critical 1p deletion region function to maintain neuroblastoma survival and activate *MYCN* transcription.[301,302] *ALK* kinase domain mutations and gene amplifications have been demonstrated in hereditary neuroblastoma that may otherwise be underscored by *PHOX2B* germline mutation.[117-119,303,304] About 15% of sporadic neuroblastomas also show aberrations of ALK,[117-119,305] suggesting that ALK inhibitors might be useful therapeutically in neuroblastoma. SNP variations at 6p22.3,[306] 2q35 (the *BARD1* gene),[307] and copy number aberration at 1q21 (the *NBPF23* gene)[308] are associated with increased risk for development of neuroblastoma but without further elucidation of the likely mechanisms involved biologically.

Rhabdoid Tumor

Malignant rhabdoid tumors generally have dismal outcomes, particularly those presenting in infancy, and most cases, whether arising in soft tissues, kidney, or CNS (where they are known as atypical teratoid/rhabdoid tumors), have deletions of the chromosome 22 long arm, targeting the *SMARCB1* (*INI1)* tumor suppressor gene. Biallelic *SMARCB1* mutation is present in the vast majority of rhabdoid tumors, with frequent truncating mutations occurring. In a small number of cases, instead of *SMARCB1,* the *SMARCA4 (BRG1)* gene is inactivated.[309] *SMARCB1* encodes a member of the SWI/SNF protein complex involved in chromatin remodeling.[310,311] Chromosome 22 deletion is often the only detectable cytogenetic aberration, suggesting that *SMARCB1* inactivation is an early oncogenic event in these remarkably aggressive tumors,[312,313] which are classically diploid and genomically stable.[314,315] Indeed, sequencing studies have revealed a remarkably simple tumor genome otherwise with virtually no oncogenic mutations identifed.[315,317] Additional evidence of an essential tumorigenic role includes the finding of germline *INI1* mutations in some individuals with rhabdoid tumors[311,318,319] and the development of rhabdoid tumor models in mice with inactivating *SMARCB1* mutations.[320] Notably, germline *SMARCB1* mutations are not restricted to rhabdoid tumors but have been implicated also in familial schwannomatosis[321] and in nonrhabdoid CNS tumors, including medulloblastoma.[318] and multiple meningiomas[322] SMARCB1 inhibits cyclin D1 expression by recruiting a histone deacetylase 1 complex to the *CCND1* (cyclin D1) promoter, resulting in G1 cell cycle arrest.[323] The relevance of cyclin D1 in *SMARCB1*-mediated tumorigenesis is underscored by the observation that rhabdoid tumors develop in SMARCB1+/– mice expressing cyclin D1 whereas SMARCB1+/– mice with cyclin D1 deficiency (cyclin D1–/–) do not develop rhabdoid tumors.[324] These observations suggest that drugs targeting cyclin D1 might be relevant for rhabdoid tumors,[325] and clinical trials testing this are planned.

Recent work has unraveled an epigenetic antagonism between SMARCB1 and Polycombs of the PRC2 complex.[326] The Polycomb proteins are transcriptional repressors that modulate chromatin structure to silence gene expression, and they are key regulators of cell fate transitions. Their function frequently becomes deregulated in cancer.[327] The Polycombs have been shown to be required for the repression of differentiation genes in stem cells[328,329] so that this repression of differentiation might be facilitated by loss of the PRC2 antagonist SMARCB1.

Rhabdoid tumors are characteristically composed of cells with vesicular nuclei and prominent nucleoli, with the nucleus often being pushed to an eccentric location within the cell by a dense intracytoplasmic inclusion (see Fig. 45-9), which, as seen by electron microscopy, consists of a tightly arranged whorl of intermediate filaments. These filaments stain nonspecifically for various markers, giving the tumor a polyphenotypic appearance. Absence of SMARCB1 expression in the tumor cells but not the normal stromal support nuclei, as is readily demonstrable by immunohistochemistry, is useful for diagnosing rhabdoid tumor (see Fig. 45-9).[31,330]

Alveolar Soft Part Sarcoma

Alveolar soft part sarcoma is a rare tumor, occurring mostly in adolescents and young adults, with a predilection for involvement of soft tissues in the head and neck region. However, other soft tissue and even hollow viscera may be involved. Characterized by a distinctive morphology, with nested or alveolar-like growth, the tumor cells are epithelioid, with abundant clear to eosinophilic cytoplasm, sharply defined cellular borders, and diastase-resistant, periodic acid–Schiff (PAS)-positive intracytoplasmic crystals (Fig. 45-25), which on electron microscopic examination are rhomboidal. Alveolar soft part sarcoma generally exhibits indolent behavior but nonetheless has a high risk for late metastases and indeed represents the sarcoma most likely to metastasize to the CNS.[331] There are no histologic features to predict clinical behavior. The classic cytogenetic feature of ASPS is t(X;17)(p11;q25), producing fusion of the *ASPSCR1* and *TFE3* genes.[332] This same translocation is seen in a subset of pediatric renal cell carcinomas, with the distinct difference that the *ASPS*-related translocation is *un*balanced and involves gain of Xp telomeric to *TFE3* and loss of 17q sequence telomeric to q25[333] while the renal carcinoma–associated translocation is balanced. The ASPSCR1-TFE3 fusion protein induces strong expression of MET tyrosine kinase in tumor cells.[334] Antibody raised to the carboxyl terminus of TFE3 produces strong nuclear reactivity in *ASPSCR1-TFE3* fusion-positive tumors.[335]

Nonmesenchymal Solid Tumors

Renal Tumors

Most pediatric renal tumors contain characteristic cytogenetic aberrations. Deletion of 11p is a well-known aberration in Wilms tumor, but several other aberrations, including extra copies of chromosome 12, are more frequent and have apparent prognostic relevance, as does LOH of 1p and 16q.[336,337] Another pediatric renal tumor with consistent cytogenetic aberrations is congenital cellular mesoblastic nephroma, in which various chromosomal trisomies and oncogenic fusion of the TEL and NTRK3 proteins are observed reliably.[7,250] More recently, it has emerged that translocation-associated carcinomas make up a majority of pediatric renal carcinomas.[338,339] In addition, neuroblastoma patients are at hugely increased risk (329-fold)[340] of developing oncocytoid renal carcinoma[341]; however, pediatric renal carcinoma may also follow certain sarcomas.[342,343]

Pediatric Renal Cell Carcinomas with Xp11 or 6p21 Translocations. Pediatric renal cell carcinomas are uncommon and they generally have a papillary morphology, accompanied by translocations involving chromosomes X or 6.[344] By comparison, adult papillary renal cancers typically have a distinctive profile of chromosomal trisomies, although a rare few contain the same translocations seen in pediatric renal cancers. The

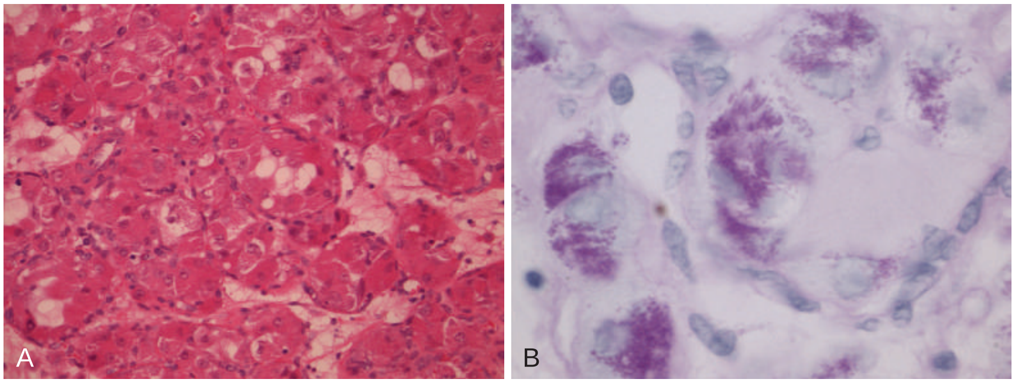

Figure 45-25 Characteristic histologic features of alveolar soft part sarcoma include an alveolar-like arrangement of cells with abundant deeply eosinophilic cytoplasm (**A**) and diastase-resistant, periodic acid–Schiff-positive intracytoplasmic crystals (**B**).

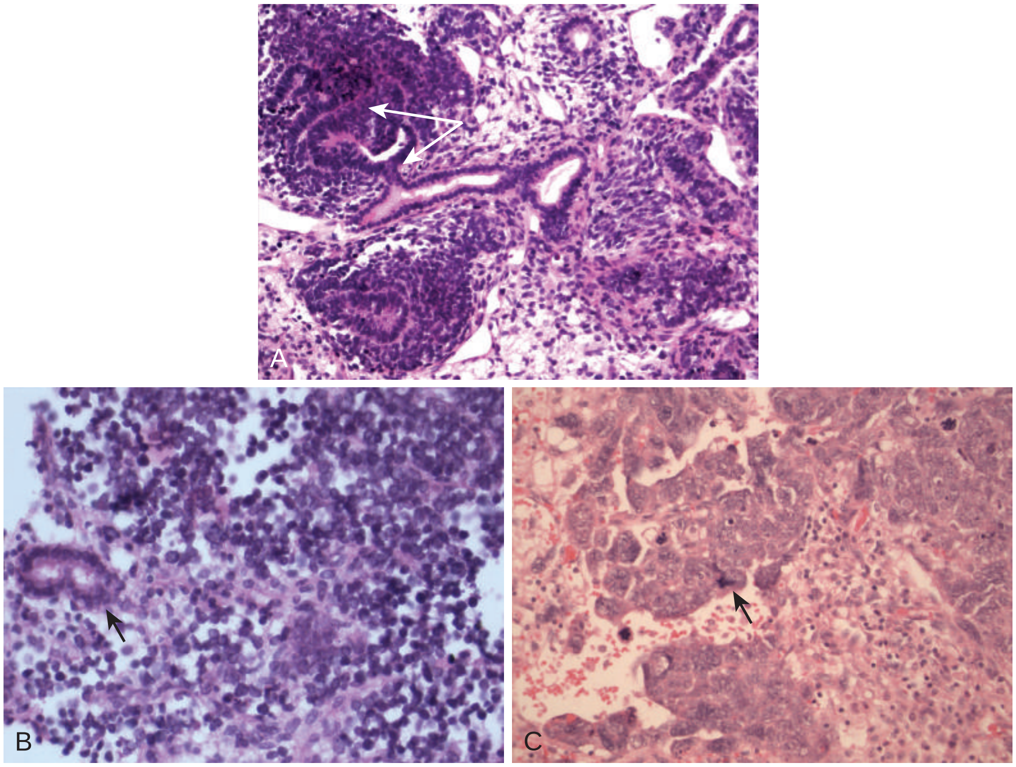

Figure 45-26 **A,** Wilms tumor with triphasic histology. The tumor recapitulates nephrogenesis with condensation of mesenchyme at tips of tubular branch-points. Here, the blastema is condensed around a focus of tubular differentiation *(arrows)*. **B,** High-power image showing undifferentiated blastema, which in the absence of obvious tubular differentiation *(arrow)* might be difficult to distinguish from other undifferentiated small round cell tumors. **C,** Anaplastic Wilms tumor with bizarre mitoses and massively enlarged hyperchromatic nuclei *(arrow)*.

unifying theme for the pediatric carcinoma translocations is that they target various members of the MiT family of transcription factors. These include t(X;1)(p11;q21), resulting in fusion of *PRCC* (at chromosome band 1q21) and the MiT family member *TFE3* (at chromosome band Xp11). There are variants of this translocation, including t(X;17)(p11;q25), in which *TFE3* is fused with the *ASPSCR1* gene at chromosome band 17q25.[345] Also involving an MiT family member is t(6;11)(p21;q13), which fuses *TFEB* (at chromosome band 6p21) with the *Alpha* gene (at chromosome band 11q13).[346] The *TFEB*-rearranged tumors more consistently express melanocytic markers HMB45 and Melan A than do *TFE3*-translocated cases.[347] TFE3 and TFEB immunostains, respectively, show specific reactivity in a nuclear distribution in the correspondingly rearranged cases but may rarely be negative in the presence of molecular proof of a translocation, and a robust FISH assay has also been developed to confirm rearrangement of *TFEB*.[347] Intriguingly, however, whereas ASPS cases with ASPSCR1-TFE3 fusion were found to uniformly express cathepsin K, a target of MiTF, and the majority of PRCC-TFE3 rearranged carcinomas did similarly, the ASPSCR1-TFE3 fusion-positive carcinomas were all negative for cathepsin K,[348] a feature that might be exploited in certain diagnostic settings.

Wilms Tumor. Wilms tumors are the most common type of renal cancer in children. They typically contain primitive blastemal cells that differentiate into tubular epithelial, glomerular, and/or mesenchymal populations. The classic triphasic Wilms tumor contains an admixture of blastemal, epithelial, and mesenchymal components (Fig. 45-26), and all three cell types may contain the same clonal chromosomal aberrations.[349] Various genetic alterations are found in subsets of Wilms tumors, including trisomies 6, 8, 12, and 18, and deletions of 11p13 (see later). Deletions of 11p15, 1p, and 16q bode ill in patients with low-stage favorable histology tumors and 1q gains are associated with relapse. These can all readily be tested on interphase nuclei by FISH assay (see Table 45-1).[337,350-352]

Deletion 11p13 is the most extensively characterized cytogenetic aberration in Wilms tumors. This aberration became the focus of many studies after reports that individuals with the WAGR syndrome (***W***ilms, ***A***niridia, ***G***enitourinary abnormalities, and mental ***R***etardation) often had constitutional deletions at chromosome band 11p13, harboring the Wilms tumor suppressor gene *(WT1)*.[244,245] WAGR phenotype, however, results from deletions of several genes, with the *WT1* gene deletion responsible for predisposition to Wilms tumors and with deletion of a neighboring gene, *PAX6,* responsible for aniridia.[246] Although most or all WAGR-associated Wilms tumors have complete inactivation of *WT1,* such inactivation is found in fewer than 20% of sporadic Wilms tumors, and here again it appears to function as a tumor suppressor gene, the homozygous deletion of which is essential for Wilms tumorigenesis.[353] Familial Wilms tumor predisposition is rare and primarily linked to loci on 17q or 19q and only uncommonly to *WT1*.[354,355] Approximately 7% to 30% of Wilms tumors have deletion of the *WTX* gene, which notably is the first putative tumor suppressor gene identified on chromosome X.[247-249] *WTX* loss, invariably a somatic event in Wilms tumor, results from truncating mutations or more commonly from deletion of the corresponding region on the single copy of chromosome X in males, although there is controversy as to whether the deletion in females invariably involves the active copy of chromosome X.[250,251] Interestingly, although germline mutation of WTX is associated with osteopathia striata congenita with cranial sclerosis, these patients have no increased risk for developing Wilms tumor.[356] The WTX protein promotes β-catenin ubiquitination and degradation,[254] and it is therefore expected that *WTX* gene deletions in Wilms tumors would hyperactivate WNT–β-catenin signaling pathways. This is in keeping with the finding of virtually mutual exclusivity of β-catenin mutations (found in about 15% Wilms tumors) and *WTX* mutations.[255-258] On the other hand, CTNNB1 (protein)-stabilizing mutations largely overlap with inactivating mutations of *WT1*[357,358] but occur later in oncogenesis. The suggestion has been made that WTX inactivation, although frequent in Wilms tumor, is a late event and of unclear clinical significance.[359]

Loss of heterozygosity (LOH) or loss of imprinting (LOI) of 11p15 is seen in approximately 70% of Wilms tumors and leads to upregulation of IGF2,[359-361] which occurs through biallelic expression of IGF2 owing to germline mutation of imprinting in Beckwith-Wiedemann syndrome.[362,363]

Nephrogenic rests—persistent islands of uncompleted organogenesis believed to represent precursor lesions—are found in surrounding kidney in approximately 30% of sporadic Wilms tumors and almost all bilateral or multifocal Wilms tumors.[364,365] These may take the form of intralobar or perilobar nephrogenic rests (ILNR and PLNR, respectively), each being associated with particular histologic phenotype[364,366] and genetic mutations, such that PLNRs are more commonly blastema rich, associated with overgrowth syndromes and show aberrations in the 11p15 imprinted region, whereas ILNRs typically are rich in stroma, including skeletal muscle or adipose elements, are associated with Denys-Drash and WAGR syndromes, and have *WT1* or β-catenin mutations.[367,368]

Various cytogenetic findings are associated with anaplastic histology in Wilms tumor. Complex karyotypes with chromosome counts in the triploid to tetraploid range are generally found in tumors with diffuse or focal anaplasia.[259] Similarly, Wilms tumors with *TP53* tumor suppressor gene mutations generally show anaplasia (see Fig. 45-26),[260] a finding linked more with therapy resistance than to a more biologically aggressive phenotype per se.

Clear Cell Sarcoma of the Kidney. Also formerly known as bone-metastasizing renal tumor, clear cell sarcoma of the kidney lacks any specific immunomarker and may show very variable histological features, making diagnosis a potential challenge. This tumor has a propensity to occur in boys younger than age 5 years.[369,370] Until recently, virtually nothing was known about the biology of this tumor of unfavorable histology, apart from individual case reports of a t(10;17)(q22;p13) recently characterized to show a fusion of the gene encoding the 14-3-3 ε family member of ubiquitously expressed modulators of phosphoserine-containing proteins (YWHAE) with *NUTM2* genes on 10q22, which encode proteins that are related to the NUT protein (see later).[371] This transcript was found to be expressed in 12% of clear cell sarcomas of the kidney and is similar to the translocation underpinning high-grade endometrial stromal sarcoma.[372] Although the full functional consequences of this translocation remain to be elucidated, upregulation of CCND1 is a feature in high-grade endometrial stromal sarcoma bearing YWHAE-FAM rearrangements.[372]

Mesoblastic Nephroma. Mesoblastic nephromas are the most common renal tumors diagnosed in infancy and may rarely also be encountered in older children. Histologically, mesoblastic nephroma falls into two categories: those tumors composed of bland, benign-appearing spindle cells interdigitating with the surrounding tissues, essentially recapitulating the morphology of fibromatosis, are known as classic mesoblastic nephroma,[261] whereas those with greater cellularity, sometimes in a fascicular arrangement, that are well delineated with a pushing border and composed of cells with plump nuclei, less cytoplasm, more mitoses, blood lakes, and often zonal necrosis, are known as cellular mesoblastic nephroma (Fig. 45-27; see Fig. 45-16).[262] Trisomy 11 is a consistent cytogenetic aberration in mesoblastic nephromas but is found only in the cellular group.[187,263] Approximately 70% of cellular mesoblastic nephromas contain trisomy 11, often accompanied by trisomies for chromosomes 8 and 17.[187] By contrast, clonal chromosomal aberrations have not been identified in classic mesoblastic nephroma. These findings suggest that trisomy 11, with or without other clonal chromosomal aberrations, is associated with

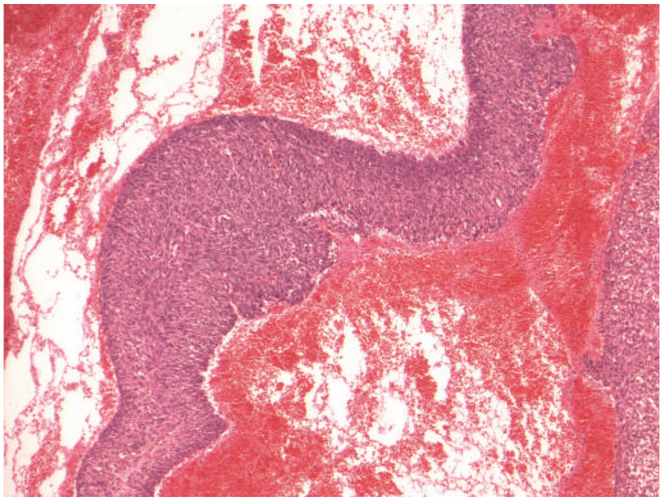

Figure 45-27 Cellular congenital mesoblastic nephroma with prominent blood lakes.

progression from classic to cellular histology in mesoblastic nephroma.[187] Mesoblastic nephromas with trisomy 11 generally also contain a balanced translocation t(12;15)(p13;q26), resulting in oncogenic fusion of the *TEL* and *NTRK3* genes. The t(12;15)(p13;q26) is cryptic by cytogenetic evaluation using chromosomal banding but is readily demonstrable by FISH or RT-PCR (see Fig. 45-2). These cytogenetic associations have been useful diagnostically, because Wilms tumors (the entity most likely confused with mesoblastic nephroma on small biopsy when blastema only has been sampled) rarely have trisomy 11 and have not been found to bear t(12;15).[241,242]

NUT Midline Carcinomas

Based on initial case reports, NUT midline carcinoma was considered a malignancy of children and adolescents arising in midline structures, especially upper aerodigestive tract and thymus.[110,373,374] Midline origin below the diaphragm is now well recognized, and the entity may also present in adulthood.[375,376] With the exception of an isolated atypical case,[377] all reported patients have died of disease or treatment complications within months of diagnosis. The histologic appearance is variable, typically including undifferentiated cells but often accompanied by immunohistochemical evidence of epithelial differentiation and, in some cases, with histologically convincing squamous differentiation (see Fig. 45-15). This entity was initially defined by the midline location, undifferentiated carcinoma–like histology, highly lethal course, and characteristic cytogenetic feature of t(15;19) (see Fig. 45-1). The t(15;19) results in oncogenic fusion of the *BRD4* (bromodomain-containing) and *NUT* genes on chromosomes 19 and 15, respectively, encoding a BRD4-NUT fusion oncoprotein. A subset of NUT midline carcinomas features similar oncogenic mechanisms in which *NUT* is fused with *BRD3*, or with yet unidentified translocation partners.[375] Diagnosis can be confirmed by karyotypic demonstration of t(15;19), molecular cytogenetic demonstration of *NUT* gene rearrangement, or RT-PCR demonstration of *BRD4-NUT* or *BRD3-NUT* fusion oncogenes.[375,376,378] The oncogenic function of BRD3-4-NUT oncoproteins is not yet well understood and the normal function of NUT is unknown. Interestingly, however, the NUT fusion oncoproteins do appear to block squamous differentiation in epithelial cell precursors.[378]

Thyroid Carcinomas

Thyroid malignancies include medullary carcinoma, which may be sporadic, or familial in the setting of multiple endocrine neoplasia type IIA (MEN-IIA) and MEN-IIB with germline *RET* tyrosine kinase gene mutations. Papillary thyroid carcinomas may also be sporadic, but are encountered with greatly increased frequency in individuals exposed to radiation, including adults after external-beam irradiation and children exposed to radioactive fallout, as from the Chernobyl disaster. Regardless of the patient's age or exposure to radiation, papillary carcinomas can feature chromosomal rearrangements resulting in oncogenic *RET* fusions.[70,379] *BRAF* mutations, on the other hand, although found in many adult papillary thyroid carcinomas, are uncommon in childhood thyroid carcinomas.[380,381] Follicular thyroid carcinomas are uncommon but are associated with a diagnostic translocation t(2;3), resulting in oncogenic fusion of the *PAX8* and *PPAR*γ genes (see Fig. 45-14).[108]

Blastomas

The central tumorigenic role of RB1 inactivation in retinoblastoma has served as a paradigm for tumor suppressor genes in oncology, but little is known of the other genetic mechanisms responsible for tumor progression in this disease. Recently, specificity of the cone-rod homeobox-containing gene *(CRX)* as an immunohistochemical marker for metastatic retinoblastoma versus other extracranial small round blue cell tumors was described.[383] Similarly, the molecular underpinnings of hepatoblastoma, pancreatoblastoma, and pleuropulmonary blastoma are only poorly understood. Trisomies of chromosomes 2 and 8 are found in many hepatoblastomas and pleuropulmonary blastomas,[384,385] but the genes targeted by these trisomies have not been identified. The identification in patients with familial pleuropulmonary blastoma of germline inactivating mutations of *DICER1*, an RNAse endonuclease essential in the processing of microRNAs,[386,387] has led to the recognition of a "DICER1 syndrome," predisposing patients to a wide variety of tumors, notably pleuropulmonary blastoma, cystic nephroma, and ovarian Sertoli-Leydig tumors.[388] The risk for tumors, however, is low, because most mutation carriers do not develop tumors. In contrast to the classic tumor suppressor model, monoallelic loss of DICER1 predisposes to tumor development through haploinsufficiency whereas loss of the second allele is inhibitory.[389,390]

Central Nervous System Tumors

Although heritable syndromes, including neurofibromatosis 1 and 2, von Hippel-Lindau syndrome, tuberous sclerosis, Li-Fraumeni syndrome, Gorlin syndrome, and Turcot syndrome account for a minor proportion of childhood CNS tumors, they have provided considerable pathogenetic insights including the important roles of Wnt, SHH, and TP53 pathways in medulloblastoma, for example.[391] Medulloblastomas are now, on a molecular basis, categorized into four groups based on alterations of SHH and Wnt pathways.[392-396] Dysregulation of Notch and HGF/MET pathways are also important in medulloblastoma. It has long been known that isochromosome 17 i(17)q was a common aberration in medulloblastoma and correlates with poor clinical outcome.[397,398] Further, cytogenetic aberrations also occur in medulloblastoma and many of these can be established by FISH assay, which has been used to generate a molecular stratification system from worst to best, including *MYC/MYCN* amplification, 6q gain, 17q gain, 6q/17q balance, and 6q loss.[397] Catastrophic DNA rearrangements were reported in pediatric medulloblastoma in the context of TP53-associated chromothripsis.[399] Meanwhile, high-resolution SNP arrays have identified recurrent copy number alterations indicative of epigenetic modification contributing to tumorigenesis[400] and evidence is emerging of a role for microRNA dysregulation also contributing.[400,401] Recently, somatic copy number aberration analysis has shown novel potentially targetable alterations in medulloblastoma including transforming growth factor β (TGF-β) and nuclear factor κB (NF-κB) signaling pathways.[402] In supratentorial PNET, deletion of *CDKN2A* was associated with metastatic progression[403] and amplification of *KIT* and *PDGFRA* have been described in some cases also,[404] potentially providing therapeutic targets. Recently, considerable further progress has been made in understanding supratentorial PNET (also known as CNS PNET).[405] Copy number and gene expression analyses detected three molecular subgroups of sPNET: primitive neural, oligoneural, and mesenchymal lineage based on differential expression of cell lineage markers Lin28 and OLIG2 with distinct survival and metastatic characteristics. These markers can be evaluated by immunohistochemistry.

Many genetic alterations have been identified in ependymoma without further pointers as to candidate genes until recent studies,[406-409] which have helped generate three subsets of ependymoma. Until very recently little if anything was known about the biology of diffuse pontine gliomas, because these are rarely sampled. Oligo array CGH conducted on archival postmortem cases has now provided initial insights into this tumor.[410] Response predictors identified in oligodendroglioma include amplification of *EGFR* (epidermal growth factor receptor) at 7p12 and homozygous deletion of *CDKN2A* at 9p21, which correlate with poor response to chemotherapy and reduced survival.[411] *EGFR* amplification in high-grade gliomas and amplification of *PDGFRA* in 15% malignant pediatric gliomas similarly call for investigation of its role as a molecular therapeutic target in that tumor.[412,413] More than half of pilocytic astrocytomas bear tandem duplications, translocations, or activating mutations of *BRAF*, which are associated with improved prognosis.[414-417]

Germ Cell Tumors

Many germ cell tumors contain a diagnostic cytogenetic marker, isochromosome 12p, often found in the context of a moderately complex karyotype, among other clonal chromosomal aberrations (Fig. 45-28).[418] Isochromosome 12p results from duplication of the chromosome 12 short arm on either side of the centromere and is uncommon in carcinomas and sarcomas.[419] Therefore demonstration of isochromosome 12p, particularly in any poorly differentiated cancer, should provoke strong suspicion of a germ cell origin.

Hematologic Neoplasms

Hodgkin Lymphoma

Hodgkin disease (HD), first described by Thomas Hodgkin in 1832, remained a poorly understood disease for over a century and a half, largely because of the sparse nature of neoplastic cells (typically <1%) within the tumor mass, even raising occasional doubt as to

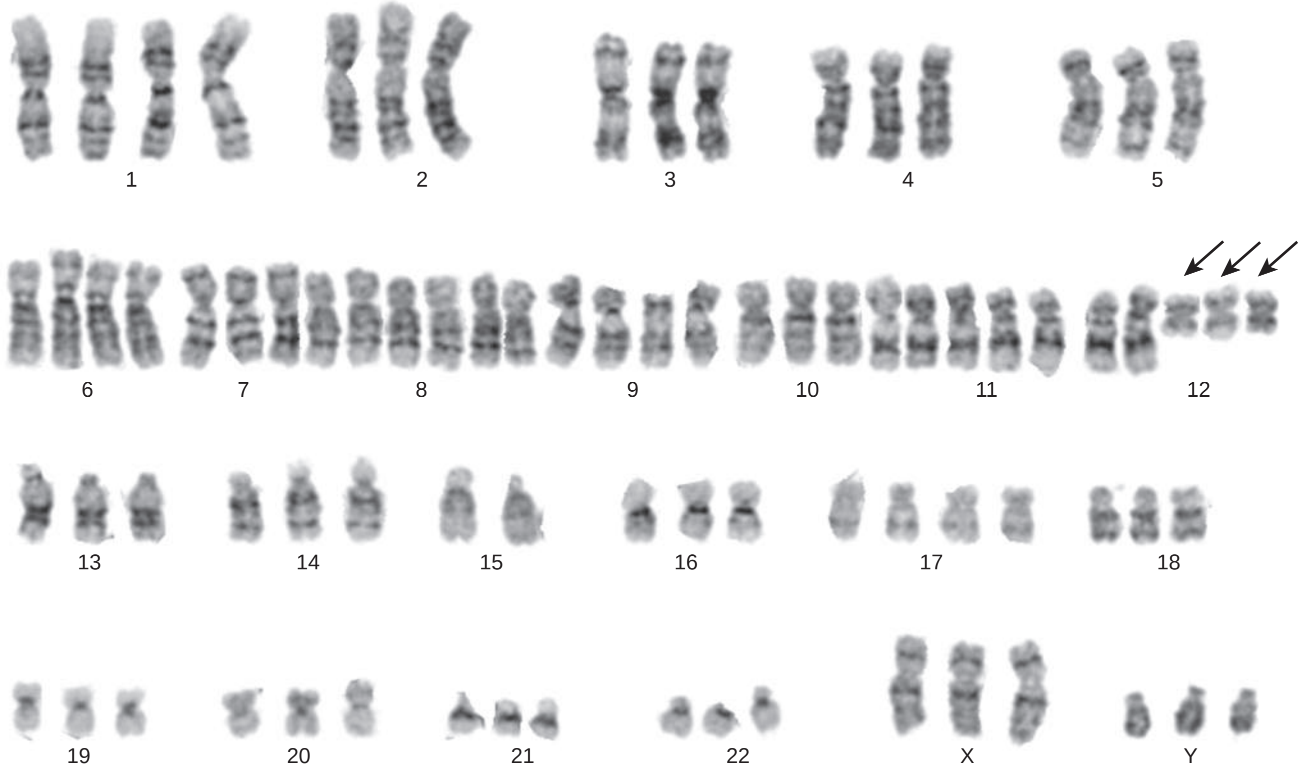

Figure 45-28 Malignant germ cell tumor karyotype showing three copies of the pathognomonic isochromosome 12p *(arrows)*.

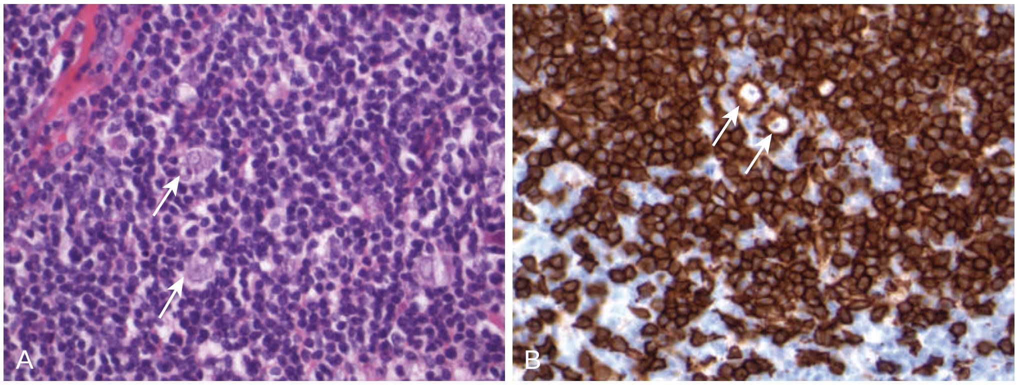

Figure 45-29 Nodular lymphocyte-predominance Hodgkin lymphoma featuring lymphocyte and histiocyte popcorn neoplastic cells (**A**, *arrows*) among small reactive lymphocytic infiltrate, and with immunohistochemical reactivity for the CD20 pan-B marker in both reactive and neoplastic cells (**B**, *arrows*).

the neoplastic nature of the entity. This sparseness of malignant cells, combined with their poor proliferative index, confounded attempts to investigate the molecular basis of HD. Karyotypic evaluations have been challenging, but nonetheless yielded early insights into the nature of HD. The capacity to grow Hodgkin cells continuously in vitro and the fact that injection of these cells into athymic nude mice produced tumors supported a neoplastic nature,[420] as did the aneuploid karyotypes demonstrated in Hodgkin lymphoma (HL) cell cultures.[421]

Light microscopic examination has permitted morphologic assignment of HL into classic and nodular lymphocyte-predominance subtypes,[422-424] a categorization recognized by the World Health Organization (WHO); this provided an attempt at cell of origin classification. The nodular lymphocyte-predominant subtype features a lymphocyte and histiocyte (L&H) neoplastic cell population, also known as popcorn cells (Fig. 45-29), with B-cell immunophenotype—expressing CD45, CD20, and BCL6 but lacking CD15 and CD30—whereas classic Hodgkin-Reed-Sternberg (H-RS) cells show only equivocal expression of the pan–B-cell marker CD20 and lack CD45 reactivity but express CD15 and CD30 in a membrane and Golgi staining pattern (Fig. 45-30).[425,426] Classic HL is subclassified into nodular sclerosis, mixed cellularity, lymphocyte-depleted, and lymphocyte-rich variants, depending on the composition of the background nonneoplastic elements in the tumor. The lack of any obvious

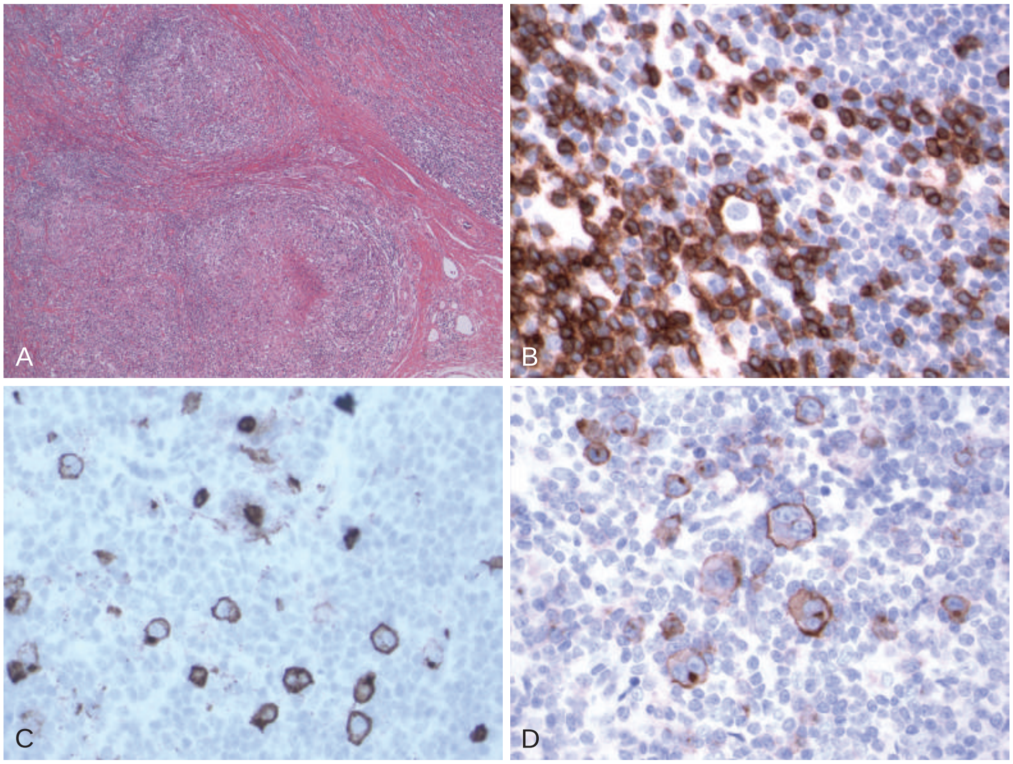

Figure 45-30 Nodular sclerosis Hodgkin lymphoma showing prominent fibrotic bands (**A**) and rimming of characteristic Reed-Sternberg cells by CD57+ lymphocytes (**B**). The Reed-Sternberg elements show cell membrane and Golgi expression of CD15 (**C**) and CD30 (**D**).

physiologic counterpart, together with its otherwise noncommittal immunophenotype, initiated a search to reveal the true nature of the H-RS cell, and molecular studies have assisted substantially in these efforts (see later).

Substantial insights into HL pathogenesis have come from single-cell studies showing that L&H and the vast majority of H-RS cells are B cells and clonal in nature.[427] These neoplastic H-RS cells seem to be of germinal center B-cell derivation,[428] with 96% featuring clonal *IG* rearrangements but lacking *IG* gene transcripts because of defects in *IG* gene regulatory elements. These findings apply in both Epstein-Barr virus (EBV)-associated and EBV-unassociated HL.[429] L&H cells express BCL6, in keeping with a germinal center differentiation stage, whereas H-RS cells express CD138 (syndecan), more in keeping with a postgerminal center differentiation stage.[430] Single-cell studies of H-RS cells have shown clonal *IG* gene rearrangements supporting a B-cell phenotype in 95% of cases. Even the 15% of HL with H-RS cells expressing T-cell markers generally contain clonal *IG* gene rearrangements and, overall, only 1% to 2% of classic HL cases have clonal *TCR* gene rearrangements.[431-434] Thus T-cell marker expression is generally considered aberrant in H-RS cells.

Both classic and nodular lymphocyte-predominance HL (NLPHL) are characterized by chromosomal instability, which is manifest by extremely complex cytogenetic aberrations in the neoplastic cells.[435] Molecular cytogenetic studies typically demonstrate chromosomal aberrations in the hyperdiploid range.[436]

Nodular Lymphocyte-Predominance Hodgkin Lymphoma. The observation that NLPHL corresponds to germinal center stage B-cell differentiation is in keeping with the finding of recurrent *IGH-BCL6* fusions, resulting from t(3;14)(q27;q32).[437] HL karyotyping evaluations have not revealed IGH region 14q32 rearrangements in NLPHL; these aberrations are undoubtedly being masked by the overall complexity of the HL karyotypes, with the recurring t(3;14) being cytogenetically cryptic.[438] However, molecular cytogenetic studies have demonstrated *BCL6* rearrangements in almost 50% of NLPHL.[437,439-441] CGH analyses in NLPHL have underscored the genomic complexity of these tumors, with frequent copy number gains involving chromosomes 1, 2q, 3, 4q, 5q, 6, 8q, 11q, 12q, and X and copy number losses for chromosome 17.[442] The copy number gains involving 2q, 4q, 5q, 6, and 11q are otherwise uncommon in hematologic neoplasia, and therefore might signify genomic aberrations of unique importance in the pathogenesis of NLPHL.

Classic Hodgkin Lymphoma. In classic HL, gains of 2p and 9p are identified in 30% to 50% of cases and 12q aberrations are also noted.[443] FISH studies have confirmed that the aberrations involve the locus of the *JAK2* gene at 9p23-24[444] and *MDM2* at 12q14-15.[445,446] The 2p copy number gains, which involve the *REL* gene (encoding one of the five subunits of NF-κB), might contribute to constitutive NF-κB activation, which is a hallmark of HL.[447]

Evaluations of *IG* gene aberrations in classic HL have demonstrated *IGH, IGL,* and *IGK* rearrangements in 17%, 3%, and 1% of cases, respectively.[448] These rearrangements juxtaposed the *IG* loci with genes at 2p16 *(REL),* 3q27 *(BCL6),* 8q24 *(MYC),* 14q24, 16p13.1, 17q12, and 19q13.2 *(BCL3-RELB)*. *IGH-BCL6* fusions were found in 4 of 70 cases, although a previous study had not shown such events in 40 cases of nodular sclerosis and mixed cellularity classic HL.[441] t(14;18), resulting in the typical *IGH-BCL2* fusion, has been reported in one case of follicular lymphoma evolving into Hodgkin lymphoma.[449]

Non-Hodgkin Lymphoma

Non-Hodgkin lymphomas (NHLs) account for 7% to 10% of all pediatric malignancies. Cytogenetic and molecular genetic aberrations have been studied extensively in adult NHL, but there have been few comparable studies in pediatric NHL, with the exception of well-characterized *MYC* gene rearrangements in Burkitt lymphomas. Most pediatric NHLs belong to one of four overall categories: Burkitt (40%), lymphoblastic (30%), large B-cell (20%), and anaplastic large cell (10%). Cytogenetic hallmarks include *MYC* rearrangements in Burkitt lymphomas, 14q11 rearrangements in T-cell lymphoblastic leukemia and lymphomas, and *ALK* rearrangements in anaplastic large cell lymphomas.[450] The proposed WHO classification of lymphoid neoplasms incorporates the Revised European American Lymphoma (REAL) classification, which takes into account morphologic, immunophenotype, genetic, and clinical features. Notably, there can be marked differences in molecular mechanisms and clinical response when comparing pediatric with adult forms of the same NHL subtype. For example, adult large B-cell lymphomas are heterogeneous entities, many of which have a phenotype suggesting follicular center cell origin and containing *IGH* region translocations that upregulate the *BCL2* or *BCL6* genes. Pediatric large B-cell lymphomas, by contrast, generally have gene expression and immunophenotypic features of germinal center cell origin and lack *IGH-BCL2* rearrangements but have a better prognosis than adult cases.[451] Lymphoblastic lymphomas are on a biologic continuum with ALL, and the biology of this subtype is discussed in the later section on ALL.

Burkitt Lymphoma. The cytogenetic underpinnings of Burkitt lymphoma were first reported in 1972, when Manolov and Manolova described aberrations of the chromosome 14 long arm[452]; these were later shown to represent t(8;14)(q24;q32), resulting in rearrangement of the *IGH* gene with the chromosome 8q *MYC* oncogene region.[14,453] *IGH-MYC* rearrangements are found in approximately 80% of Burkitt lymphomas, irrespective of whether the tumors are EBV positive or EBV negative and whether they are sporadic or arise in an endemic region.[454] However, *IGH-MYC* rearrangement can be found rarely in diffuse large cell lymphomas, so this cytogenetic aberration is not diagnostic of Burkitt lymphoma. Alternative cytogenetic mechanisms dysregulate *MYC* transcription by juxtaposing *MYC* with the κ or λ *IG*

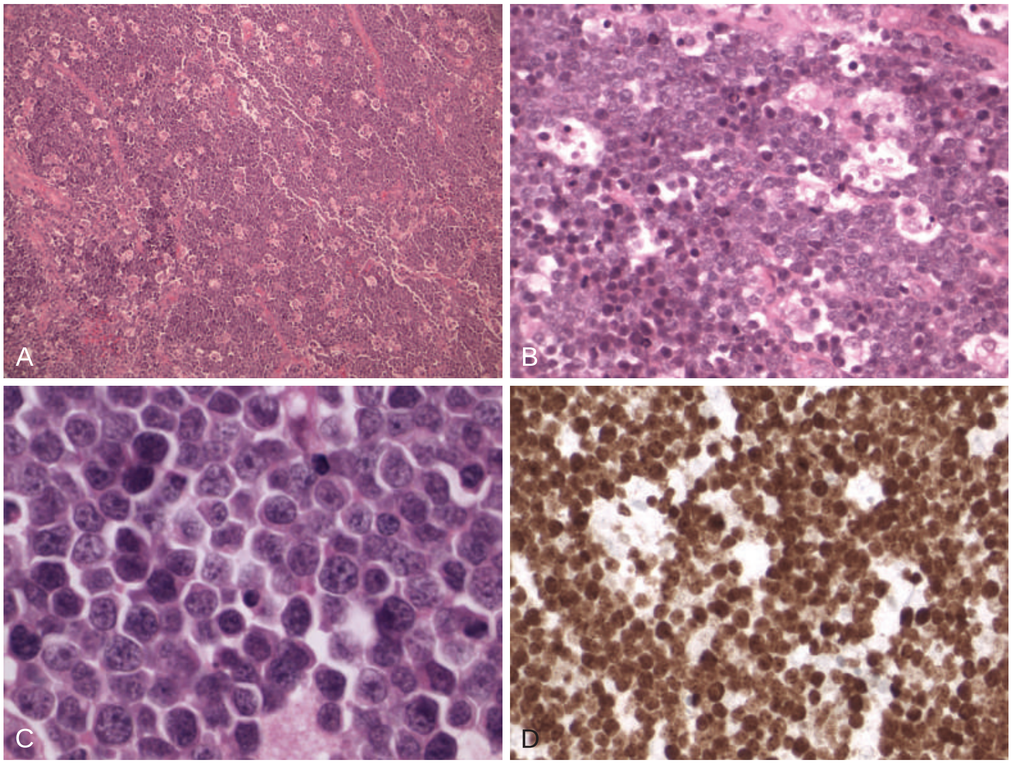

Figure 45-31 Burkitt lymphoma low-power (**A**) and intermediate-power (**B**) views show starry sky appearance resulting from engulfment of cellular apoptotic debris by interspersed macrophages; higher-power view shows typical squaring off of cells from one another (**C**). The Ki-67 proliferation marker is expressed strongly by almost 100% of the lymphoma cells (**D**).

gene loci.[455] The κ and λ *IG* rearrangements result from t(2;8) and t(8;22), which are found in 5% and 15% of Burkitt lymphomas, respectively.

Burkitt lymphoma has a characteristic cytomorphologic appearance in which the cells are squared off from each other. A starry sky appearance results from engulfment of cellular apoptotic debris by interspersed macrophages, whereas the actual neoplastic cells have relatively uniform intermediate-sized nuclei and exhibit at least a 99% proliferative index, as demonstrated by immunostaining for Ki-67 (Fig. 45-31). *MYC* region genomic breakpoints vary between the endemic and sporadic types of Burkitt lymphoma. The breakpoints in endemic Burkitt lymphomas can be as much as 300 kb upstream or downstream of the *MYC* coding sequences, whereas those in sporadic Burkitt lymphomas typically involve the first exon or first intron of *MYC*.[455] Despite this considerable variability in genomic breakpoint location, all the rearrangements serve the purpose of dysregulating *MYC* expression and can be detected by a simple dual-color *MYC* break-apart FISH assay, in which the probe components are more than 300 kb upstream and downstream of *MYC*, thereby flanking most *MYC* region translocation breakpoints (Fig. 45-32). Secondary cytogenetic aberrations occur in conjunction with *MYC* translocations in some Burkitt lymphomas. Several of these, particularly 1q duplication and 13q deletion, may be associated with worse prognosis, although the numbers of patients studied have been few.[456]

Follicular Lymphoma. Follicular lymphoma is uncommon in childhood. When diagnosed, it more commonly affects boys and presents as localized disease in lymph nodes or tonsils. Such cases generally lack *BCL2* rearrangement and BCL2 expression.[457]

Diffuse Large B-Cell Lymphoma. Diffuse large B-cell lymphomas may be categorized into germinal center, activated B-cell–like, or primary mediastinal types. In children, diffuse large B-cell lymphomas are frequently of the germinal center type and associated with an overall better prognosis than for adults. Despite the germinal center phenotype, however, diffuse large B-cell lymphomas in children generally lack t(14;18), which is seen in a proportion of adult cases of this subtype.[451]

Anaplastic Large Cell Lymphoma. ALCLs are predominantly mature T-cell disorders with excellent prognosis in the pediatric population.[458] ALCL is a diagnostic pitfall for the pathologist, although the morphology is uniquely different from all other hematopoietic malignancies. The cells often appear relatively cohesive and have abundant cytoplasm, so they may mimic an epithelial neoplasm more so than suggesting a lymphoid one; ALCLs, furthermore, classically express epithelial membrane antigen (Fig. 45-33). The cells typically react for CD30 and often also express the anaplastic ALK receptor tyrosine kinase protein (see Fig. 45-33), which is constitutively activated by oncogenic fusions to various partners containing

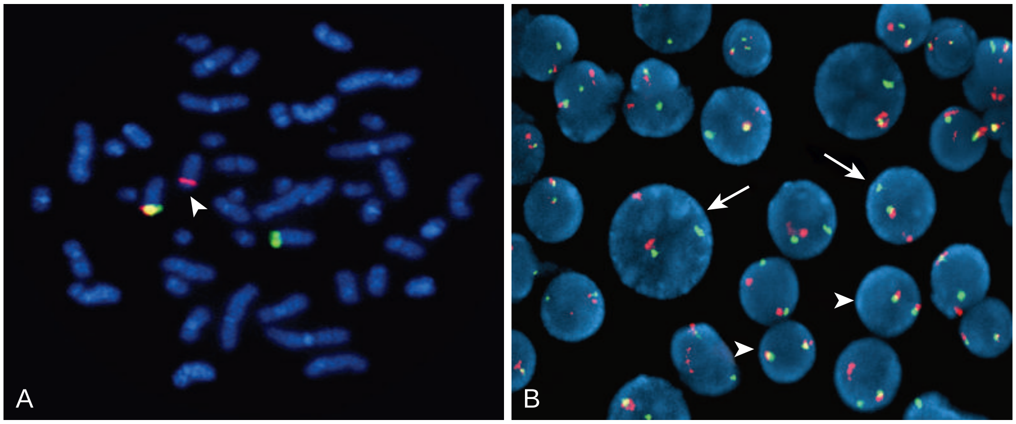

Figure 45-32 Burkitt lymphoma fluorescence in situ hybridization (FISH) using *MYC* break-apart probe in metaphase cell (**A**) and interphase cells (**B**) from malignant pleural effusion in a 5-year-old child. The metaphase cell shows a t(8;14), indicative of *IGH-MYC* fusion, in which the centromeric *(red)* and telomeric *(green)* FISH probe components localize to chromosomes 8 *(arrowhead)* and 14, respectively. The interphase cells include *MYC*-rearranged Burkitt lymphoma *(arrows)* and reactive nonneoplastic lymphocytes *(arrowheads)*.

dimerization domains. The most common of these fusions, found in 80% of ALCLs, results from t(2;5) fusing the 3′ end of the *ALK* gene to the 5′ end of *NPM*,[459] and serving as a useful diagnostic marker of ALCL. Less common *ALK* fusions involve *ATIC, TFG, CLTC, TPM3, TPM4,* and *MSN.*[116,460-462] ALCL occurs in a cutaneous form, which is usually ALK-negative, whereas nodal and extranodal systemic forms express ALK in about 95% of pediatric cases. ALK encodes a receptor tyrosine kinase that is normally expressed in neural cells of the intestine, testis, and brain but not in nonneoplastic lymphoid cells. A smaller number of pediatric ALCLs are B-cell disorders, and these cases often feature oncogenic fusions of the *ALK* and clathrin genes.[458] The pattern of ALK immunostaining in association with *ALK-NPM1 (NPM)* fusion resulting from t(2;5) is one of nuclear and cytoplasmic staining, with distinctive nucleolar accentuation (see Fig. 45-33). Similarly, other ALK oncoproteins are associated with distinctive immunostaining patterns, including the granular cytoplasmic staining with clathrin-*ALK*

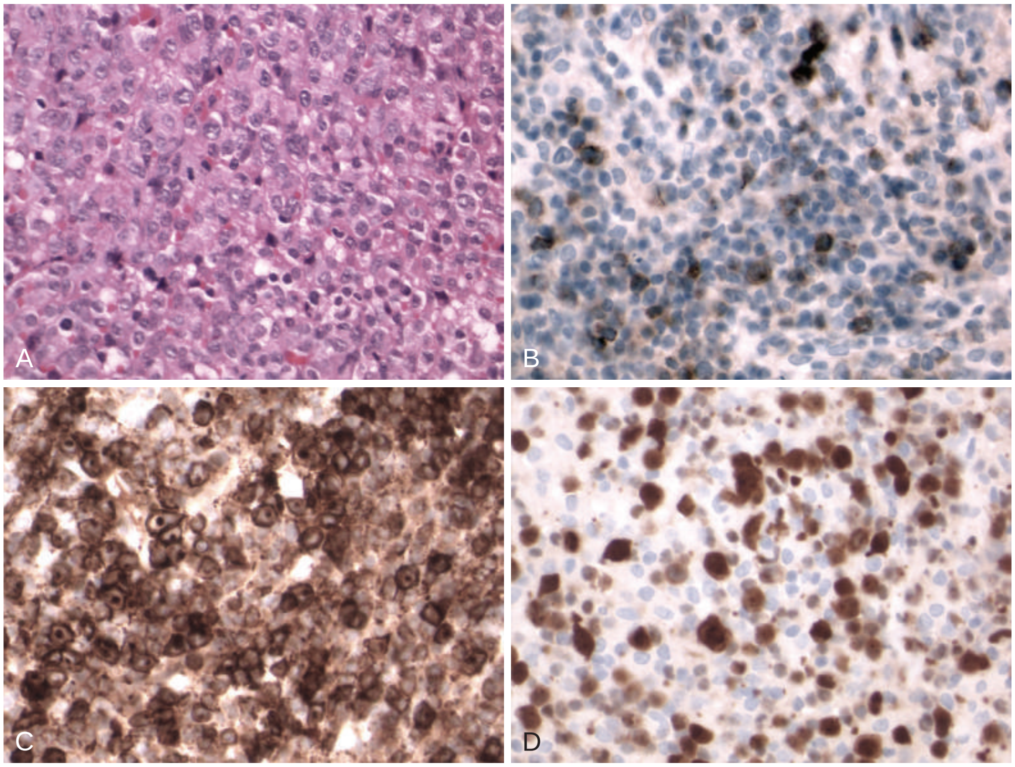

Figure 45-33 In anaplastic large cell lymphoma, histologic features include cohesive cells with abundant cytoplasm, imparting an epithelioid appearance (**A**). Immunohistochemical features include patchy expression of epithelial membrane antigen (**B**), strong membrane and Golgi reactivity for CD30 (**C**), and anaplastic lymphoma kinase immunostain (**D**), which in this t(2;5)-positive case shows reactivity in both nuclear and cytoplasmic compartments.

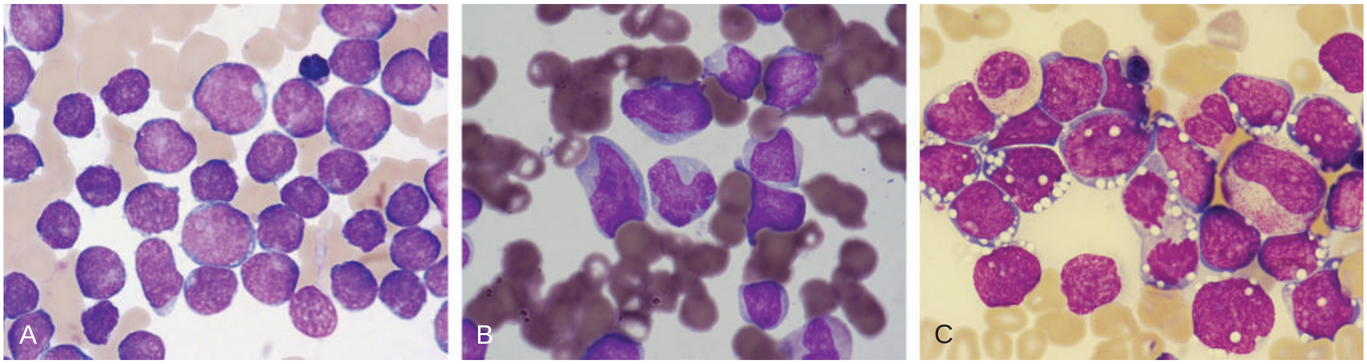

Figure 45-34 Acute lymphoblastic leukemia historical French-American-British subtypes. **A,** L1, with smaller, more uniform cells and a high nuclear-to-cytoplasmic ratio. **B,** L2, with somewhat larger cells, and a more varied nuclear-to-cytoplasmic ratio. **C,** L3 (Burkitt), with larger cells and numerous vacuoles. *(Courtesy Marybeth Helfrich, Children's Hospital of Philadelphia.)*

rearrangement, diffuse cytoplasmic staining in the case of *TFG-ALK* and *ATIC-ALK* rearrangements, diffuse membranous and cytoplasmic staining with *TPM3-ALK,* and nuclear membrane staining with *RANBP2-ALK* rearrangement. However, *ALK* staining is not specific for ALCL. As noted earlier (see "Mesenchymal Neoplasms: Soft Tissue and Bone Tumors"), *ALK* oncoprotein expression is also characteristic of inflammatory myofibroblastic tumors. In the hematopoietic group of neoplasms, *ALK* reactivity as an indicator of clathrin-*ALK* fusion oncoproteins also has been described for large B-cell neoplasms.[463]

Subcutaneous Panniculitic T-Cell Lymphoma. This lymphoma subtype produces firm nodular infiltrates of skin, which occasionally progress to ulceration. These infiltrates are generally confined to subcutaneous fat, with sparing of the overlying dermis and epidermis. Other helpful histologic features include evidence of cellular atypia and characteristic rimming of adipocytes by the neoplastic cells. In the presence of such histologic features, demonstration of *TCR* gene rearrangement confirms the diagnosis.

Hepatosplenic T-Cell Lymphoma. This is an extranodal lymphoma of γδ T-cells. Clinical presentation is generally that of hepatosplenomegaly without accompanying lymphadenopathy, although other anatomic locations, typically also extranodal, may be involved. The histologic findings on a diagnostic liver biopsy may mimic those of hepatitis. The neoplastic infiltrate is sinusoidal in distribution, sparing the portal tracts. Expansion of the sinusoids by a monotonous lymphoid population should prompt consideration of this diagnosis. Demonstration of *TCRγ* gene rearrangement is confirmatory, and another helpful genetic feature, seen in many cases, is the cytogenetic finding of isochromosome 7q,[464,465] often accompanied by trisomy 8.[466] Development of hemophagocytic syndrome may ensue and heralds poor outcome.

Acute Lymphoblastic Leukemia

ALL, the most common childhood cancer, comprises a heterogeneous spectrum of diseases characterized by clonal proliferations of lymphoid precursor cells at varying stages of development but traditionally assigned to one of three FAB subtypes (Fig. 45-34). Classic teaching has been that the ALL cell of origin is a committed lymphoid progenitor, with the particular stage of lymphoid differentiation during which the transforming event occurs being highly variable. However, although controversial, studies have suggested that leukemic transformation in ALL may occur in a more primitive stem cell.[467] Irrespective of whether the nonneoplastic cell that is targeted for transformation is a committed lymphoid cell, the major demonstrable immunophenotypic ALL subsets are B- or, less often, T-cell precursors. About 85% of cases are B-cell precursor ALL, whereas 10% to 15% are T-cell precursors. Expression of the CD10 B-cell differentiation antigen characterizes common ALL, which is the most frequent form of childhood ALL (Fig. 45-35). By contrast, the vast majority of cases of ALL in infants (defined as <1 year old) are negative for CD10 cell surface antigen expression. Burkitt leukemias, with their characteristic phenotype of mature B-cell surface IG expression, account for only approximately 0.5% of cases of childhood ALL.[2] Heterogeneous primary molecular genetic aberrations cause leukemic transformation and are associated with distinctive biologic properties and clinical features in the different major subtypes of childhood ALL.

Intralocus *IG* and *TCR* Gene Rearrangements. Historically, the patterns of *IG* and *TCR* gene rearrangements in pediatric ALL have provided insights into the ordered hierarchy of rearrangements of *IG* and *TCR* genes in lymphoid maturation.[468,469] The diversity of rearrangements of variable (V), diversity (D), and joining (J) segments generated within these loci in the human immune response affords a signature of unique markers of lineage, clonality, and maturation stage in each ALL. This is particularly true because *TCR* gene rearrangements can be identified even in precursor B-cell ALL and, conversely, *IG* gene rearrangements can occur in T-cell ALL. Furthermore, *IG* and *TCR* gene rearrangements are not static but can evolve after leukemic transformation via subclone progression (e.g., from D-J to complete V[D]J assembly or from *IGH* to *IGK* light-chain gene

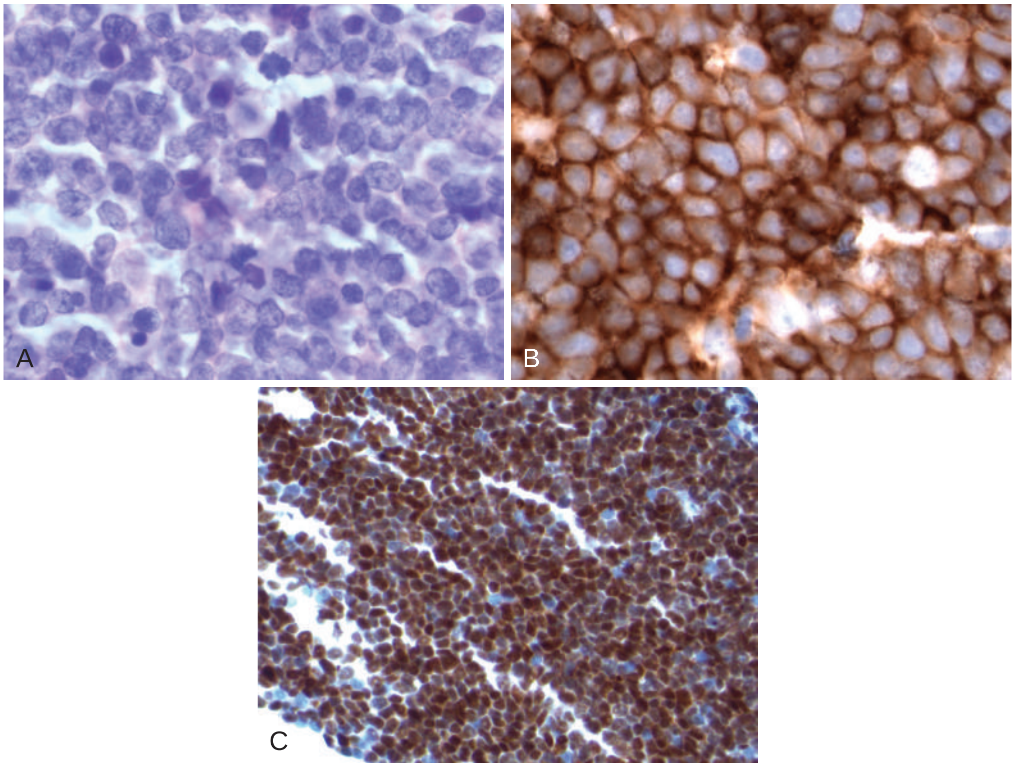

Figure 45-35 **A,** Lymph node infiltration by pre–B-cell acute lymphoblastic leukemia lacking any appreciable cytoplasm and with slightly irregular nuclear contours. The nuclear chromatin is finely dispersed. This case shows typical strong immunohistochemical staining for CD10 (common ALL antigen) (**B**) and nuclear TdT expression (**C**).

rearrangement).[470] However, because of the related nature of the ALL subclones in any given patient, *IG* and *TCR* gene rearrangements can serve as sensitive markers for detecting minimal residual disease and predicting relapse.[471,472] Comparable sensitivity in detecting minimal residual disease can also be achieved by multiparameter flow cytometric analysis of various antigens, expression of which is restricted to leukemic cells.[473]

One study has suggested that about 25% of cases of B-cell precursor ALL undergo transformation at the pro–B- to pre–B-cell stage, characterized by cytoplasmic μ expression and assembly of the pre–B-cell receptor complex. The pre–B-cell differentiation stage is a critical cell survival checkpoint because most normal B cells cannot form intact immunoglobulin and instead undergo apoptosis.[474] The subset of ALL transitioning from pro-B to pre-B cells exhibits steroid sensitivity.[474]

Interlocus *IG* and *TCR* Gene Rearrangements and Translocations. Not only do *IG* and *TCR* genes undergo intralocus rearrangements, but their aberrant recombination also causes interlocus chromosomal translocations and inversions. These chromosomal rearrangements can create hybrid antigen receptor genes when two different antigen receptor loci recombine with each other. A small fraction of pediatric ALLs of B- or T-cell lineage harbor these hybrid antigen receptor gene rearrangements.[475] Alternatively, chromosomal rearrangements can juxtapose transformation-inducing non-*IG*/non-*TCR* genes with the regulatory enhancer and promoter elements of *IG* or *TCR* genes as a second type of interlocus rearrangement. V(D)J recombination errors of this type,[476] causing transcriptional upregulation of the juxtaposed non-*IG*/non-*TCR* genes, occur in subsets of pediatric ALL, especially in T-cell ALL.

SIL-SCL rearrangements and *SCL* translocations disrupting *TCR* genes are present in approximately 30% of cases of T-cell ALL overall. The *SCL (TAL1)* gene at chromosome band 1p34, which encodes a basic helix-loop-helix (bHLH) transcription factor, was first discovered at the t(1;14)(p34;q11) breakpoint junction involving the *TCRαδ* locus in a stem cell leukemia.[477] Other T-cell ALL cases harbor a different type of *SCL* rearrangement, in which illegitimate V(D)J recombinase activity at recombinase-like signal sequences in *SCL* and *SIL* (SCL-interrupting locus) creates an interstitial deletion on chromosome 1p. The *SIL-SCL* rearrangement causes aberrant regulation of *SCL* expression by the *SIL* promoter.[478,479] The t(1;3)(p34;p21) translocation, fusing *SCL* and the nonantigen receptor gene *TCTA,* is mediated by a similar mechanism of illegitimate V(D)J recombinase activity.[480]

In other recurrent translocations in T-cell ALL, various oncogenic transcription factor genes such as *LMO1, LMO2, LYL1,* and *HOX11 (TLX1)* are fused to different *TCR* loci, leading to unscheduled expression of the relevant transcription factor protein.[78] *LMO2* translocations occur in 10% to 20% of T-cell ALLs. Microarray experiments have shown that oncogenic transcription factor genes can be overexpressed in T-cell ALL subsets at distinct maturation stages and are prognostic markers, even when conventional karyotyping studies do not reveal such translocations.[481] For example, dual-color FISH analysis and a ligation-mediated PCR assay have revealed cryptic translocations of the *HOX11 (TLX1)* gene with the *TCRD* locus in most T-cell ALLs in which there was high *HOX11* expression.[482] This finding is particularly intriguing because high-level *HOX11* expression in T-cell ALL correlates with a favorable prognosis.[482] In addition, the CD34–, CD1a+, CD4/CD8 double-positive cortical immunophenotype has suggested that the immature β pre-αβ stage of maturation arrest is associated with high *HOX11* expression.[482] These results have demonstrated that molecular cytogenetics can provide more sensitive and consistent evaluations of ALL oncogenic mechanisms compared with conventional karyotyping.

The most recently identified example of a recurrent *TCR* gene translocation in T-cell ALL is t(6;7)(q23;q34), which juxtaposes the *MYB* gene at chromosome band 6q23 with the *TRB* locus.[483] Although the subtelomeric locations of *TRB* and *MYB* precluded recognition of this rearrangement by conventional karyotyping, the rearrangement is readily detectable with methods such as FISH, Southern blotting, or PCR assay.[483] Molecular cloning has revealed a heptamer-like sequence adjacent to the translocation breakpoint in the *MYB* gene, consistent with illegitimate V(D)J recombinase activity as the mechanism of this translocation. In this translocation, placement of *MYB* in close proximity with the *TRB* enhancer regulatory element results in aberrant expression of the translocated *MYB* allele and a gene expression signature consistent with upregulation of various proliferation and mitosis genes.[483] t(6;7) is of clinical interest because the median age of the patients is only 2.2 years old,[483] which is unusual because T-cell ALL is otherwise infrequent in young children. This translocation exemplifies the importance of cooperating mutations in pediatric ALL pathogenesis, because many cases of T-cell ALL with t(6;7) also contain *NOTCH1* mutations and *CDNK2A (p16^{ARF})* deletions.[483] Dysregulated *MYB* expression in T-cell ALL of the very young can also result from gene duplications, as demonstrated by molecular and fiber FISH analyses of *MYB* gene copy number.[483] *MYB* is expressed at high levels in the thymus, and it has been suggested that *MYB* deregulation results from sustained rather than ectopic expression[483]; in that sense, it differs from several other transcription factor oncogenes disrupted in T-cell ALL.

Another T-cell ALL translocation, t(7;9)(q34;q34.3), fuses *TCRB* to the gene encoding the NOTCH1 transmembrane receptor protein, which regulates T-cell maturation.[484] This is an extremely uncommon translocation, occurring in less than 1% of cases of T-cell ALL; however, it was more recently shown that at least 50% of T-cell ALL cases have activating intragenic *NOTCH1* mutations, including cases with other major translocations.[485] Activating *NOTCH1* mutations affecting the extracellular heterodimerization domain result in ligand-independent activation, whereas those affecting the intracellular PEST (proline [P], glutamic acid [E], serine [S], and threonine [T]) domain cause increased stability of the protein. The mutant NOTCH1 protein is a potential therapeutic target of gamma secretase inhibitors, which can block NOTCH1-mediated signaling in T-cell ALL.[485] Inhibition of NOTCH1 signaling by gamma secretase inhibitors is associated with upregulation of the phosphatase and tensin homologue (PTEN) tumor suppressor protein.[486] Although a phase I/II clinical trial of γ secretase inhibition did not show efficacy in T-cell ALL, the observed drug resistance could be attributed in part to *PTEN* gene deletion. PTEN inhibits the PI3K/AKT pathway, and loss of PTEN function is associated with AKT activation and a switch in oncogene addiction from the NOTCH1 to the AKT signaling pathway. *PTEN* mutational analyses have indicated that a subset of T-cell ALL (8%) harbors mutations of this gene at diagnosis, independently or together with *NOTCH1* mutations, or, alternatively, the *PTEN* mutations can be secondary alterations associated with disease progression.

Analogous to the interlocus *TCR* gene rearrangements in T-cell ALL, molecular approaches have also been revealing in precursor B-cell ALL, and recurrent novel translocations that juxtapose *IG* genes with oncogenic transcription factor genes have been identified and characterized. One recent example is the t(6;14)(p22.3;q32.22) that fuses the joining region of the *IGH* gene with the gene encoding *ID4*.[487] The translocation causes overexpression of the ID4 bHLH transcription factor and is associated with a CD19+, CD10+, HLADR+, TdT+ common precursor B-cell immunophenotype, low-risk clinical features, and favorable prognosis.[487] This translocation is often accompanied by deletion of the chromosome 9p genes *CDKNA* and *PAX5,* suggesting cooperativity of these alterations in the pathogenesis of this disease.[487] Another example of *IGH* gene rearrangement is seen with t(5;14), which occurs in less than 1% of cases of precursor B-cell ALL. t(5;14) places the *IL3* gene under transcriptional regulatory control of the *IGH* locus, resulting in the hallmark clinical feature of peripheral eosinophilia associated with this translocation.[78]

In the rare entity of Burkitt leukemia, expression of *MYC* is altered by translocation into the *IGH* or, less often, the *IGK* or *IGL* light chain locus, but oncogenic transformation at a more mature B-cell developmental stage is reflected by IgM expression on the leukemia cell surface.

Another area of interest has been in the application of molecular approaches to determine the temporal origins of ALL-specific *IG, TCR,* or transcription factor gene rearrangements. Studies of ALL in monozygous twins and studies of ALL molecular cytogenetic aberrations in neonatal Guthrie blood spots have been useful in indicating whether various ALL subtypes arise before or after birth. In the case of T-cell ALL there is recent evidence that the disease is not initiated in utero or that the clonal aberration in most cases is present below the detection sensitivity of PCR at the time of birth.[488] However, these findings are in contrast to PCR-based findings on *TCR* gene rearrangements in two other studies, which were consistent with a prenatal origin of T-cell ALL.[489,490] In one of three cases of T-cell ALL with *NOTCH1* mutation, the *NOTCH1* mutation was detectable in neonatal

Guthrie blood spot DNA, whereas the *SIL-SCL* rearrangement in the same case occurred later as a postnatal event.[491] Thus ALL-specific *IG* and *TCR* gene rearrangements and/or leukemia-associated transcription factor alterations in at least some T-cell ALLs are in utero events, even though the latency to clinically evident disease can be protracted. Most subtypes of precursor B-cell ALL also initiate in utero (see later).

Chromosomal Translocations Not Involving *IG* or *TCR* Genes

TEL-AML1 ***Translocations.*** Several of the major recurrent chromosomal translocations in pediatric ALL do not involve *IG, TCR,* or other genes with obvious V(D)J recombination signal sequences. The most frequent chromosomal translocation in all pediatric cancers[492] is t(12;21), which is present in 25% of cases of CD10+ B-cell lineage common ALL. This translocation is cryptic by conventional Giemsa-banded karyotyping and must be detected by FISH or molecular analyses. The leukemogenic fusion of the *TEL (ETV6)* gene from chromosome band 12p13 to the *RUNX1 (AML1)* gene from chromosome band 21q21 is associated with recruitment of complexes containing histone deacetylases to AML1 target genes, causing aberrant transcriptional repression.[493] There is evidence that t(12;21) occurs as an in utero event[493,494] in cells that are at a stem or B-cell progenitor developmental stage, before *IG* and *TCR* gene rearrangement. Rearrangement of the immune receptor loci occurs after the initiating *TEL-AML1* translocation.[495] *TEL-AML1* translocations occur in cord blood specimens of healthy neonates at 100 times the incidence of *TEL-AML1* translocations in leukemia, indicating that progression to overt ALL is rare in *TEL-AML1*–positive cells. Similarly, the low concordance (5% to 10%) of *TEL-AML1* leukemia in monozygous twins has suggested that postnatal mutations are required for transformation of *TEL-AML1*–positive progenitor cells into frank ALL.[496] These additional mutations often include loss of the normal *TEL* allele.[492] The *TEL-AML1* translocation is associated with a favorable outcome.[492]

TCF3 (E2A) ***Gene Translocations.*** t(1;19) occurs in approximately 5% of cases of pediatric ALL, fusing the *E2A* gene on chromosome band 19p13.3 to the *PBX1* gene on chromosome band 1q23. This translocation is most often found in cIg+ (pre-B) rather than cIg– B-cell precursor ALL (25% vs. <1% of cases).[497] t(1;19)(q23;p13.3) is associated with a poor prognosis in the cIg+ (pre-B) cases. *E2A* is a critical B-cell developmental gene that encodes an IG enhancer binding protein. The *E2A* gene encodes three different bHLH transcription factors via alternative splicing of the *E2A* transcript. The *PBX1* gene product is a homeobox transcription factor, and t(1;19) results in the production of a fusion oncoprotein from the der(19) chromosome, in which the DNA-binding domain of PBX1 replaces the carboxyl DNA-binding bHLH domain of *E2A*. t(1;19)(q23;p13.3) is detectable in neonatal Guthrie cards in only about 10% of cases, suggesting a postnatal origin, and is different in that sense from the other major subtypes of pediatric ALL.[496,498] Split-signal FISH using different color probes for the *E2A* and *PBX1* genes is a useful tool for the definitive identification of this translocation,[499] which is otherwise indistinguishable karyotypically from a different translocation sharing breakpoints in the same chromosome bands. The alternate form of t(1;19)(q23;p13.3) in ALL does not disrupt the *TCF3 (E2A)* and *PBX1* genes but rather fuses the *DAZAP1* RNA-binding protein gene on chromosome band 19p13.3 to the *MEF2D* DNA-binding protein gene on chromosome band 1q23.[500]

A rare t(17;19) *E2A* variant occurs in 1% of cases of childhood B-cell precursor ALL, which creates a *E2A-HLF* (hepatic leukemia factor) fusion gene. t(17;19) is associated with coagulation abnormalities and has a poor prognosis.[497]

BCR-ABL1 ***Translocations.*** About 5% of cases of B-cell precursor ALL harbor t(9;22)(q34;q11), fusing *BCR* with the *ABL1* tyrosine kinase gene. This translocation is associated with the clinically high-risk features of older age and high white blood cell count and an especially grim prognosis.[78] However, emerging data have indicated that the molecularly targeted ABL kinase inhibitor imatinib mesylate has clinical activity against BCR-ABL+ ALL in the pediatric population as well as in adults.[501]

MLL (KMT2A) ***Translocations.*** Leukemia is the second most common malignancy during infancy. The infant cases comprise 2.5% to 5% of ALLs and 6% to 14% of AMLs in the pediatric population overall. The annual incidence of infant ALL and AML is 19 and 10/million, respectively.[133,502] Infant leukemia is a special subtype of pediatric leukemia characterized by chromosomal translocations that generate fusion oncoproteins, and 75% to 80% of cases of infant ALL and myelomonocytic-monoblastic AMLs feature balanced chromosomal translocations of the *MLL* gene at chromosome band 11q23.[503] Cases of ALL with *MLL* translocations often coexpress myeloid-associated surface antigens, especially CD15. Additionally, *MLL* translocations can be associated with true bilineal acute leukemias, in which there are separate lymphoid and myeloid cell populations (Fig. 45-36), and acute leukemias with *MLL* translocations can undergo lineage switch. *MLL* translocations are also found in secondary leukemias in patients treated with chemotherapeutic TOP2 poisons.[63] The *MLL* gene encodes a large complex oncoprotein that regulates transcription[15,504-507] and has regional amino acid similarity to that of *Drosophila* Trithorax (TRX).[132,505,506] Whereas TRX is involved in the maintenance of expression of homeotic gene complexes during embryonic development,[508] of relevance to leukemia, MLL maintains *HOX* gene expression during hematopoiesis.[509] *MLL* translocations in various types of pediatric leukemia disrupt an 8.3-kb breakpoint cluster region and fuse the 5′ portion of *MLL* with one of more than 80 different partner genes, generating diverse leukemogenic fusion oncoproteins containing the amino-terminus of MLL and the carboxyl-terminus of the partner protein.[49,68,86,510]

The native MLL protein has complex transcriptional regulatory functions. MLL undergoes proteolytic cleavage into amino- and carboxyl-segments that reassociate with one another in a multiprotein complex,[511-513]

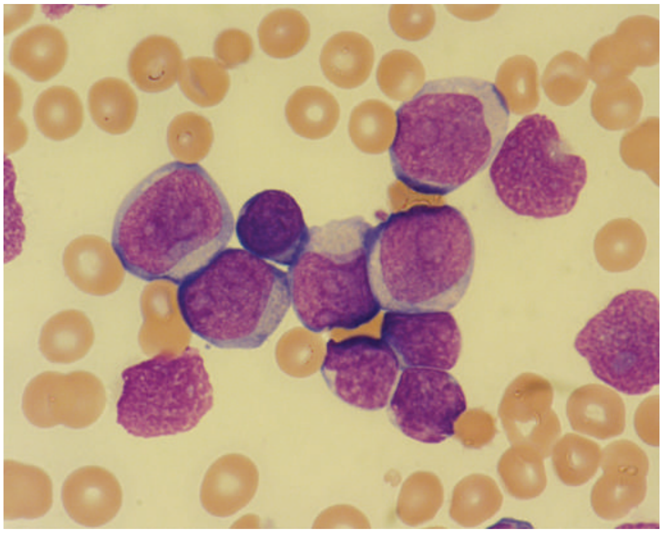

Figure 45-36 Infant bilineal acute leukemia with *MLL* translocation showing lymphoid and myeloid blast cell populations. *(Courtesy Marybeth Helfrich, Children's Hospital of Philadelphia.)*

regulating *HOX* gene expression and epigenetic modifications of nucleosomes and histones.[514] The MLL chimeric oncoproteins resulting from the various *MLL* partner gene rearrangements lack the MLL proteolytic cleavage site and affect leukemogenic transformation through transcriptional dysregulation of MLL target genes.[515] Although many *MLL* partner genes themselves encode important proteins in transcriptional regulation or cell signaling pathways,[132,515] it is unclear how the partner gene disruption contributes to leukemogenesis mediated by *MLL* translocations.

Of the approximately 75% of infant ALL cases with *MLL* translocations, 70% and 13% of cases, respectively, involve the *AF4* (chromosome band 4q21) or *MLLT1 (ENL)* (chromosome band 19p13) transcription factor partner genes.[516] In AML, the partner genes of *MLL* are much more heterogeneous, including not only genes that encode nuclear transcription factors and transcriptional regulatory proteins but also cytoplasmic proteins and proteins in various cellular organelles.[49]

MLL translocations in infant leukemias exemplify another principle in the molecular cytogenetics of pediatric leukemias, namely, the association of host risk factors and gene-environment interactions with specific aberrations. The *MLL* translocation in infant leukemia is an in utero event, the origin of which has been established by the detection of identical nonconstitutional *MLL* rearrangements in leukemias of monozygous twins,[517,518] as well as the detection of *MLL* translocations in neonatal Guthrie blood spot DNA in nontwin cases.[519] Maternal-fetal exposure from consumption of food containing TOP2–interacting substances during pregnancy has been implicated as a risk factor in *MLL*-rearranged infant AML.[520] Moreover, an inactivating polymorphism in the gene encoding reduced nicotinamide adenine dinucleotide phosphate (NADPH) quinone oxidoreductase 1 (NQO1) increases the risk for all *MLL*-rearranged infant acute leukemias, especially cases with t(4;11) fusing *MLL* to *AF4*, which are primarily ALL.[521,522] The inactivating NQO1 polymorphism is a plausible host predisposition factor because the *p*-benzoquinone detoxified by NQO1 is a TOP2 poison[523] and four-base 5′ overhangs from TOP2 cleavage lend readily to DNA damage resolution by nonhomologous end joining (NHEJ) repair, features of which usually are evident at *MLL* translocation breakpoint junctions.[47,524] Infant leukemia risk is also modulated by a genetic polymorphism in the methylene tetrahydrofolate reductase *(MTHFR)* gene; it has been suggested that the resultant increased thymidine synthesis, which enhances DNA repair, protects against *MLL* translocations.[525]

Infant ALLs with *MLL* translocations are composed of CD10– early B progenitor cells, but they may have monocytic features and they typically express the myeloid-associated CD15 cell surface antigen.[133] Clinically, *MLL* translocations are important because of their unfavorable prognosis.[516] The *MLL* translocation in infant ALL is associated with a high leukemia burden manifest as marked hyperleukocytosis, massive hepatosplenomegaly, and meningeal involvement.[133] Neonatal leukemia (leukemia in the first month of life) has an annual incidence of 4.7/million live births[526] and comprises an important fraction of leukemia in infants. The clinical manifestations of neonatal leukemia include stillbirth, signs of leukemia at birth, or hematologic abnormalities preceding the leukemia diagnosis within a few weeks.[134] Clinical hallmarks include hepatosplenomegaly, hydrops, and polyhydramnios detected antenatally, and the archetypal marked hyperleukocytosis, hepatosplenomegaly, leukemia cutis, and CNS involvement detected after birth.[134] *MLL* translocations in infant and neonatal leukemia have significant adverse effects on response to treatment, especially in cases of early B-cell lineage ALL.[44,134,516,527] The substantial adverse impact of *MLL* translocations on prognosis places infant ALL at the extreme of pediatric ALL in which outcome is the poorest.[44,134,516,527] However, in AML, in which outcome is less favorable overall than in ALL, *MLL* translocations are not independent prognostic factors. Overexpression of *FLT3* mRNA is a common secondary alteration in infant ALL with *MLL* translocations.[528] In these cases, the *FLT3* gene may be mutated or upregulated and the FLT3 protein is highly expressed.[135,529,530]

There is limited copy number variation[531] and few additional mutations have been detected, (e.g., in *NRAS, KRAS, FLT3,* and *IKZF1*[532-534]) in *MLL*-R infant ALL beyond the translocations. In contrast, altered methylation, especially hypermethylation, is a very characteristic epigenetic aberration of *MLL*-rearranged(R) ALL and the altered methylation within different subsets of *MLL*-R ALL is similar.[535]

In a microarray analysis of an infant ALL cohort (n = 97) from the COG P9407 trial representing the largest group of infants to be studied in this manner, the most significant determinant of gene expression was infant age at diagnosis.[536] Remarkably, there was a very distinct change in the gene expression pattern at approximately 90 days of age, which also corresponds with the cutoff for worst outcome. Interestingly, whereas the gene expression signature of older infants was that of a more differentiated B-cell lineage precursor, in infants younger than 90 days of age, interleukin-related genes, heat-shock proteins, and human leukocyte antigen genes linked through IL13 and IL1A were more prominent, suggesting different pathways in leukemogenesis. In addition, outcome predictors beyond age and *MLL* rearrangement status were discovered that were highly predictive of event-free survival.

Molecular Aberrations in Subsets of Precursor B-Cell ALL Identified by Integration of Gene Expression Profiling, Analysis of Copy Number Alterations, and Genomic Sequencing. The subtypes of precursor B-cell ALL that are distinguishable by distinctive cytogenetic aberrations also are able to be distinguished by their gene expression profiles. Conversely, application of integrated genomic approaches including gene expression profiling, analysis of copy number alterations, and, later, next-generation sequencing has led to the identification of clusters of precursor B-cell ALL otherwise classified as "high-risk" by conventional definition (age, white blood cells, cytogenetics) encompassing subsets with well-recognized molecular cytogenetic aberrations, such as *KMT2A* gene rearrangements and t(1;19), but also subsets lacking molecular cytogenetic markers and subsets with particularly favorable or poor outcome. For example, a cluster with 94% 4-year relapse-free survival defined by high *AGAP1, CCNJ, CHST2/7, CLEC12A/B,* and *PTPRM* expression and intragenic *ERG* deletions was identified as well as a cluster with 9.4% 4-year relapse-free survival with high *BMPR1B, CRLF2, GPR110, GPR171, IGJ, LDB3,* and *MUC4* expression and *EBF1, NUP160-PTPRJ, IL3RA-CSF2RA, SLX4IP, ADD3, IKAROS/IKZF1,* and *VPREB1* deletions.[537] The genomic basis for the differences in gene expression were subsequently elucidated and continue to be elucidated by next-generation sequencing initiatives.

Through the application of sophisticated bioinformatics algorithms, the patterns of gene expression not only have been correlated with molecular cytogenetic subtypes, but they also have been used to develop classifiers that are predictive of minimal residual disease at the end of induction and the risk for relapse within cases characterized by the presence of, for example, *JAK* mutations, kinase signatures, *IKAROS/IKZF1* deletions, or t(1;19). Whereas high expression of *RGS2, NFKBIB, NR4A3, DDX21,* and *BTG3* was associated with 87% relapse-free survival, high expression of genes including *BMPR1B, CTGF (CCN2), TTYH2, IGJ, PON2, CD73, CDC42EP3, TSPAN7,* and *SEMA6A* was associated with relapse-free survival of only 29%.[538] Additionally a 21-gene classifier in the diagnostic marrow was discerned that was able to predict the minimal residual disease burden at the end of induction.[538] Such gene expression signatures underscore the heterogeneity in gene expression within ALL in general and high-risk ALL in particular, and they are significant because they are possibly expected to have prospective therapeutic utility in the near future.

IKZF1 ***Deletions in B-Cell Precursor ALL.*** Deletion of the *IKZF1* tumor suppressor gene is present in 10% to 15% of B-cell precursor ALL. Findings from a large international study of 1128 cases of childhood B-cell precursor ALL have suggested that *IKZF1* gene deletion, as detected by approaches including PCR assay, array CGH, and Sanger sequencing, is an independent poor prognostic feature.[539]

"BCR-ABL1–*like*" *B-Cell Precursor ALL.* *IKZF1* deletions are also a frequent finding marking approximately 40% of cases of "*BCR-ABL1*-like" B-cell precursor ALL,[539] a molecular subtype of high-risk precursor B-cell ALL without *BCR-ABL1* rearrangement but with a "*BCR-ABL1*–like" gene expression signature.[540] The "*BCR-ABL1*–like" gene expression signature is estimated to be present in approximately 10% of cases of B-cell precursor ALL and approximately 15% of cases of high-risk precursor B-cell ALL and has been associated with a poor prognosis.[539-541] By mRNA-seq analysis, the "*BCR-ABL1*–like" cases were found to be characterized by cryptic chromosomal rearrangements such as *EBF1-PDGFRB, BCR-JAK2, STRN3-JAK2, PAX5-JAK2, NUP214-ABL1, ETV6-ABL1, RANBP2-ABL1,* and *RCSD1-ABL1; IGH-EPOR* fusions; *IL7R* mutations; or *SH2B3* deletion.[541] *JAK1, JAK2,* and *JAK3* mutations also have been linked to the "*BCR-ABL1*–like" gene expression signature.[542] Of therapeutic interest, consistent with the ABL1 and/or JAK/STAT signaling activation in these cases, in preclinical experiments the "*BCR-ABL1*–like" leukemias are sensitive to tyrosine kinase inhibitors (e.g., imatinib, dasatinib) as well as to the JAK2 inhibitor roxolitinib.[541]

CRLF2 ***Aberrations in Precursor B-Cell ALL.*** The "*BCR-ABL1*–like" precursor B-cell ALLs also encompass cases with *CRLF2* aberrations.[540,541] This subset of high-risk precursor B-cell ALL has surfaced through cytogenetic and FISH analyses, as well as advanced genomics studies, including microarray analysis, analysis of copy number alterations, and next-generation sequencing, and is characterized by rearrangement or mutation of the chromosome pseudoautosomal region 1 Xp22.3/Yp11.3 gene *CRLF2* (cytokine receptor-like factor 2), which encodes the TSLP (thymic stromal lymphopoietin) receptor.[543,544] *CRLF2* rearrangements are present in approximately 60% of ALL occurring in patients with Down syndrome.[545] *CRLF2* aberrations also account for approximately 8% and 15%, respectively, of pediatric precursor B-cell ALL and high-risk precursor B-cell ALL.[546-548] The *CRLF2* gene can be disrupted by rearrangements with the *IGH* locus at chromosome band 14q32, by *CRLF2* interstitial deletion resulting in *P2RY8-CRLF2* rearrangement or, alternatively, by F232C point mutation.[543,547,549] The *CRLF2* aberrations are frequently associated with *JAK1/JAK2* mutations, *IKZF1* mutations, and, less often, *IL7R* mutations. Clinically, the *CRLF2* aberrations are important because they have been correlated with a poor prognosis.[543,547] Within high-risk ALL, the poor outcome has been further linked to high minimal residual disease burden and high *CRLF2* expression.[547] They also have been linked to Hispanic/Latino ethnicity.[550] In contrast, in a recent large international study of Down syndrome ALL[545] and a number of smaller studies of Down syndrome ALL,[544] the *CRLF2* aberrations did not affect prognosis. The *CRLF2* aberrations may have further significance for therapeutic targeting because they result in sensitivity to JAK and PI3K/AKT/mTOR (mammalian target of rapamycin) signaling inhibition in preclinical models.[551,552]

iAMP21 (Intrachromosomal Amplification of Chromosome 21) in Precursor B-Cell ALL. iAMP21 is a cytogenetic abnormality that occurs in approximately 2% of B-cell precursor ALL in older children, which has a known association with inferior outcome in standard treatment protocols and for which the molecular basis has been poorly understood. In a recent analysis of leukemia cells from 94 patients with this abnormality, the common region of amplification was narrowed to a 5.1-Mb region of chromosome 21 that encompasses *RUNX1,* miR-802, and genes in the Down syndrome critical region.[553] Genomic abnormalities affecting *IKZF1, CDKN2A/CDKN2B, PAX5, ETV6,* and *RB1* also were frequently detected in these cases in addition to iAMP21.[553] Interestingly, a very detailed analysis of the heterogeneous leukemic subclones that were present and their relationships to the iAMP21 suggests that iAMP21 and not these other abnormalities was the initiating alteration and that other aberrations such as *P2RY8-CRLF2* were secondary alterations to iAMP and were acquired later in the subclones.[553] However, the specific chromosome 21 gene within the 5.1-Mb regions that is most relevant to leukemogenesis remains to be determined.

Hereditary Susceptibility to B-Cell Precursor ALL. Until recent genome-wide association studies, few heritable factors influencing B-cell precursor ALL susceptibility had been identified by candidate gene approaches (e.g., *ABCB1; MTHFR; GSTM1, GSTT1;* SNPs in *CDKN2A, CDKN2B, CDKN1A, CDKN1B* promoters; *CYP1A1*). However, a number of genetic variants modulating disease susceptibility with predilection to influence the development of particular subsets of this disease have recently been discovered. One genome-wide association study conducted on a large number of cases and controls implicated variants in three different genes as risk loci.[554] The cases studied were predominantly B-cell precursor (824 B-cell ALL, 83 T-cell ALL). The most significant variant was rs4132601 in the *IKZF1* transcription factor gene, which encodes a master regulator of lymphoid development. The rs7089424 polymorphism in the gene encoding ARID5B (AT-rich interactive domain 5B), a member of the AT-rich interaction domain family of transcription factors involved on B-cell development, was a particularly strong risk variant. A variant (rs2239633) in the gene *CEBPE,* encoding CCAAT/enhancer binding protein, epsilon, was also associated with increased risk.[554] Interestingly, the *ARID5B* variant is particularly selective for hyperdiploid ALL,[554] an association validated by a second study.[555] The latter study determined that 18 different SNPs varied in allele frequencies between cases and controls and also found that an OR2C3 variant is particularly linked to *ETV6-RUNX1* leukemia.[555] Most recently, two different polymorphisms (rs3824662 and rs3781093) in the hematopoietic transcription factor *GATA3* gene were found to significantly increase the risk for "BCR-ABL1–like" disease both relative to nonleukemia controls and relative to non–"BCR-ABL1–like" leukemia cases.[556]

Molecular Alterations in Early T-Cell Precursor Leukemia. Early T-cell precursor (ETP) ALL is a recently recognized form of T-cell ALL characterized by a CD1a−, CD8−, CD5$^{\text{weak}}$, CD34+ stem cell and CD33 and/or CD13 myeloid marker+ immunophenotype and absence of biallelic *TCRG* deletions consistent with a differentiation arrest at an immature T-cell developmental stage.[557] Whole-genome sequencing in 12 pediatric cases has shown that ETP leukemia is characterized by AML-like aberrations.[558] These include cytokine receptor and *RAS* signaling mutations affecting *NRAS, KRAS, NF1, FLT3, IL7R, JAK3, JAK1, SH2B3,* or *BRAF* in 67% of cases; inactivating mutations in hematopoietic transcription factor genes *(GATA3, ETV6, RUNX1, IKZF1)* in 58% of cases; and inactivating mutations in genes encoding histone modifying factors *(EZH2, EED, SUZ12, SETD2, EP300)* in 48% of cases, as well as other novel types of mutations not otherwise seen in T-cell ALL (e.g., *WT1, DNM2, ECT2L, RELN*).[558] Interestingly, adult ETP ALL has been shown by whole-exome sequencing to manifest mutations in *ETV6, NOTCH1, JAK1,* and *NF1;* frequent recurrent novel mutations involving *FAT1* (25%), *FAT3* (20%), and *DNM2* (35%); as well as other mutations in the *MLL2, BMI1,* and *DNMT3A* genes encoding epigenetic regulators and at least a single mutation in *DNMT3A, FLT3,* or *NOTCH1* in 60% of cases.[559] Moreover, based on gene expression profiling and cluster analysis of pediatric T-cell ALL, ETP ALL comprises a unique cluster and it has been suggested that the driving aberration in ETP leukemia involves upregulation of expression of the *MEFC2* transcription factor gene on chromosome 5q14, which is a member of the MADS-box family of transcription factors, as a consequence either of novel *MEFC2* gene rearrangements (e.g., *MEF2C-PITX2*) or of rearrangements of related factors, examples of which include *NKX2-5/BCL11B, SPI1(PU.1)/BCL11B,* and *ETV6/NCOA2* translocations.[560] The NKX2-5 regulatory protein directly binds the *MEF2C* promoter.[560] The PU.1 transcription factor controls *MEF2C* expression during lymphoid development.[560] NCOA2 is also a *MEF2C* coregulator. The ETP leukemias highly express *HHEX, LYL1,* and *LMO2,* which are MEF2C-regulated targets.[560] Interestingly, *MEF2C* has been implicated as a target gene of HOXA9 and is also highly expressed in *MLL*-rearranged AML. Yet another case was characterized by a variant reciprocal *RUNX1-AFF3* translocation with upregulated *MEF2C* expression by an unknown mechanism. ETP leukemia is clinically important because of its poor outcome.

Alterations Associated with T-Cell ALL with Cortical Arrest and a Proliferative Gene Expression Profile. The same study that identified *MEFC2* and related aberrations in ETP leukemia also has identified a novel proliferative cluster of T-cell ALL characterized by a CD1+ immunophenotype consistent with a cortical arrest, expression of cell cycle genes, and ectopic *NKX2-1* or *NKX2-2* expression, also resulting from a number of novel *NKX2-1* and *NKX2-2* gene rearrangements or *TLX1* rearrangements.[560] These include *NKX2-1* inversions to the *TCRA* or *IGH* genes, a translocation with

TCRB [t(7;14)(q34;q13)] and a *TCRD/NKX2-2* gene rearrangement. In one case, array-CGH suggested *NKX2-1* amplification due to duplication or insertion into another chromosome. The subset of cases in the proliferative cluster marked not by *NKX2-1* or *NKX2-2* rearrangement but by *TLX1* gene rearrangements are also characterized by *NKX2-1* expression. Less often there are *MYB* gene translocations in the proliferative cluster of T-ALL. This subset of leukemia is clinically important because of its more favorable prognosis.[560]

Other Clinically Important Genomic Aberrations in Acute Lymphoblastic Leukemia

FLT3 ***Mutations.*** Aberrations of the FMS-like tyrosine kinase 3 (FLT3) receptor tyrosine kinase protein are crucial oncogenic events that contribute to cellular proliferation and survival and arrested differentiation in a subset of ALL.[561,562] *FLT3* mutations have been proposed to function as secondary oncogenic events in ALL, in which there is already a proliferation-inducing primary oncogenic mutation involving another gene.[532] *FLT3* molecular aberration types include in-frame deletions and internal tandem duplications (ITDs) in the juxtamembrane region and point mutations in the activation loop of the kinase domain.[135,532,563] All of these are associated with FLT3 protein overexpression and constitutive activation of FLT3 signaling pathways through STAT5, MAP kinase, and AKT.[532,564] *FLT3*-ITD mutations are found in approximately 2% of childhood ALL,[565] and *FLT3* point mutations are found in approximately 5% and 16% of childhood B-cell lineage ALL and infant ALL, respectively.[532,565] *FLT3* mutations have a predilection for particular molecular/cytogenetic ALL subtypes, being found in 21% to 28% of cases of high hyperdiploid ALL[135,530,532] and in 18% of ALL with *MLL* gene translocations, which consequently also express high levels of constitutively active FLT3 protein.[529,530] Overexpression of the wild-type FLT3 protein is another mechanism of FLT3 activation in leukemias with *MLL* translocations,[135] and microarray analyses have demonstrated increased *FLT3* mRNA expression as a distinguishing feature of ALL cases with *MLL* translocations.[528,566] Alternatively, the expression of FLT3 ligand by leukemia cells can cause autocrine activation of FLT3 signaling by increasing constitutive FLT3 phosphorylation.[135,530,567] *FLT3* mutations are clinically important in infant ALL because they are associated with a poor prognosis.[532]

Alterations in* BCL2 *Expression. In addition to classic oncogenes and tumor suppressor genes, genes that control cell death and survival decisions are clinically important, not only in pediatric ALL but in all types of pediatric cancer because they have an impact on chemosensitivity and resistance. The intrinsic (mitochondrial) cell death pathway is regulated by the formation of homotypic and heterotypic dimers involving BCL2 and many other BCL2 family protein members with opposing pro-apoptotic or anti-apoptotic actions that collectively determine the apoptosis threshold.[568-572] Almost all cases of pediatric ALL express detectable BCL2 protein.[573] BCL2 mRNA and protein are particularly abundant in infant and pediatric leukemias with t(4;11) or other *MLL* translocations compared with ALL and AML cases without *MLL* translocations,[574] but *BCL2* expression is not exclusively a feature of *MLL* disease.[573,575,576]

CDKN2 ***Tumor Suppressor Gene Deletions.*** Chromosome band 9p21 is a site of recurring deletions in pediatric ALL. The critical deleted region at chromosome band 9p21 contains the *CDKN2A* gene, which encodes two different tumor suppressor proteins p16^{INK4A} and p14^{ARF}. The adjacent gene *CDKN2B* encodes p15^{INK4b} and is often codeleted with the *CDKN2A* gene.[577] p16^{INK4A} and p15^{INK4b} inhibit the cyclin D–dependent kinases CDK4 and CDK6.[578] Deletions of the *CDKN2B* and *CDKN2A* tumor suppressor genes at the *CDKN2* loci are present in 60% and 20% of cases, respectively, of T-cell and B-cell precursor ALL, and the p15 promoter is inactivated by hypermethylation in additional cases. *CDKN2* alterations have been implicated in relapse and poor response to treatment,[577-582] and homozygous loss of p16^{INK4A} is more frequent in pediatric ALL at relapse than at diagnosis, indicating that this aberration portends disease progression.[583] Notably, hemizygous *CDKN2A* deletion may be constitutional and confer susceptibility to leukemia and other forms of cancer.[584]

SMAD3 ***Alterations.*** Loss of *SMAD3* expression is important in the pathogenesis of pediatric T-cell ALL.[585] TGF-β is a cytokine family composed of three isoforms that have a role in tumor suppression. The *SMAD3* component protein in the TGF-β signaling pathway was discovered to be absent or barely detectable in each of 10 cases of T-cell ALL, but sequencing of the corresponding *MADH3* gene from the leukemia cells of affected patients did not reveal mutations and the mechanism of loss of *SMAD3* expression is unknown. Nonetheless, the loss of *SMAD3* impairs the growth-suppressive effects of TGF-β on T cells. *SMAD3* loss is apparently restricted to T-cell ALL and is not observed in precursor B-cell ALL or AML.[585] Deletions resulting in haploinsufficiency of the cyclin-dependent kinase inhibitor *CDKN1B (p27^{Kip1})* at chromosome band 12p12 are also recurring abnormalities in T-cell ALL,[586] and *SMAD3* loss has been demonstrated to cooperate *CDKN1B* loss in a murine leukemogenesis model.[585]

Numerical Chromosomal Abnormalities. The largest cytogenetic subset of childhood precursor B-cell ALL (approximately 30%) is characterized by a hyperdiploid karyotype, which results when nondisjunction of chromosomes causes chromosomal gains. Hyperdiploidy can be of prenatal origin, as evidenced by its presence in cord blood and neonatal Guthrie blood spots, suggesting that hyperdiploidy itself may be the initiating event in this form of ALL.[587,588] High hyperdiploid ALL (>50 chromosomes) has a favorable prognosis, especially when there are specific chromosomal trisomies, such as +4, +10, +18[589] or +10, and +17.[78,590] About 25% of cases of high hyperdiploid ALL have *FLT3* mutations, whereas other cases exhibit overexpression of the FLT3 protein through autocrine activation.[135,530]

In contrast, hypodiploidy occurs in only 6% to 8% of childhood ALL, is frequently associated with chromosomal translocations, and is a poor prognostic factor.[590,591] In one study, the adverse prognosis was especially pronounced in cases with near-haploid karyotypes containing 24 to 28 chromosomes.[590] In a more recent study there was no difference in outcome when 24 to 29, 33 to 39, or 40 to 43 chromosomes were present.[592] Nonetheless, hypodiploidy with less than 44 chromosomes is generally regarded as a marker of poor prognosis. Patients with ALL containing 44 or 45 chromosomes have a better outcome unless there is monosomy 7 or a dicentric chromosome.[592]

Importantly, the major pediatric ALL leukemia subtypes recognizable at the cytogenetic and molecular levels can now be distinguished based on their unique gene expression profiles. These broad gene expression profile differences provide new insights into ALL biology and predictive markers and might be useful in identifying novel, molecularly targeted treatments.[593]

MicroRNA Aberrations. A burgeoning class of abnormalities in cancer cells involves changes in gene expression mediated by the aberrant activity of microRNAs, which affect the translation of coding mRNAs into their respective proteins.[594,595] MicroRNAs, which are short noncoding RNAs, originate via the excision of 19 to 25 nucleotide (nt) segments after formation of a hairpin pre-microRNA loop from a larger primary pri-microRNA transcript. The base pairing interactions of microRNAs with protein coding mRNAs[595] result in microRNA-mediated translational repression. Using microRNA profiling arrays, it recently has been possible to discern unique microRNA signatures and microRNA mutations in particular leukemia subtypes.[596] For example, ALL and AML can be distinguished by differential expression of microRNAs. The microRNAs miR-128a and miR-128b are overexpressed, and the microRNAs let-7b and miR-223 are underexpressed in ALL compared with AML.[597] MicroRNAs can regulate oncoprotein expression, as shown by mir-203 regulation of BCR-ABL, as relevant in CML and BCR-ABL+ ALL.[598] It has also been suggested that microRNA signatures have prognostic relevance in leukemias in adults.[599,600] Therefore the further characterization of microRNA mechanisms has important implications for the development of new antileukemia targeted therapeutics.

Aberrant DNA Methylation Patterns in B- and T-Lineage ALL. In addition to the granularity with which recurring structural aberrations and mutations have been characterized with new developments and applications of next-generation sequencing and other genomics methods, genome-wide analysis of cytosine methylation profiles has demonstrated an overarching signature of methylation across all subtypes of B-cell lineage ALL relative to normal B cells regardless of genetic subset, but also that the different ALL genetic subtypes, whether of B- or T-cell lineage, are characterized by distinct methylation patterns.[535] The common methylation signature in B-cell lineage ALL affects cell signaling genes *(TIE1, MOS, CAMLG, GPRC5C),* cell cycle regulatory genes *(MCTS1, DGKG),* RNA metabolism genes *(PABPN1, PABPC5),* transcription factor and transcriptional regulatory genes *(PROP1, TAF3, H2AFY2, ELF5, ZBTB16, CNOT1, TADA2A),* and *HOX* genes *(HOXA5, HOXA6).* Interestingly, however, different and robust ALL clusters defined by hypomethylation and hypermethylation signatures were associated with the different genetic subtypes. At one extreme, high hyperdiploid B-ALL was the most hypomethylated, B-ALL characterized by ERG alterations was more balanced in regard to hypermethylated versus hypomethylated loci, and *CRLF2*-rearranged cases exhibited few differentially methylated regions. Moreover, the subtype-specific methylation signatures also were well correlated with gene expression patterns and there was differential methylation of genes associated with T-cell versus B-cell differentiation that were lineage dependent.[535]

However, the molecular complexity of ALL extends beyond the primary aberration, acquisition of secondary alterations, and epigenetic signatures. In a study of the molecular complexity of subclone evolution that occurs within *ETV6-RUNX1* ALL, Anderson and associates used multiplex FISH to determine in unprecedented detail the relationships of cells within leukemia subclones to one another to understand their “clonal architecture.”[601] The results suggested a tremendous amount of genetic variegation that includes continued diversification in propagating cells relative to ancestral cells in the development of subclones.[601] This genetic diversification has substantial implications for the understanding of the results of genome-wide analyses that are now more commonly being undertaken.[601]

Acute Myeloid Leukemia

Pediatric AMLs exhibit heterogeneous but characteristic clinical and biologic features, which reflect underlying molecular and cytogenetic abnormalities. Many of the characteristic AML cytogenetic aberrations are similar to those in adult AML, although the relative frequencies of the aberrations differ between pediatric and adult AML. The major FAB morphologic subtypes of AML (Fig. 45-37) are, in general, associated with typical balanced chromosomal translocations.[602] The WHO has reclassified AML based on molecular and cytogenetic aberrations, which underlie unique biologic subgroups, have clinical importance, and form the basis for assignment to appropriate treatment regimens.[603] The current WHO classification system incorporates genetic, immunophenotypic, clinical, and biologic features for diagnosis of the myeloid neoplasms.[603]

Major molecular cytogenetic aberrations in AML recognized in the WHO classification system are the following: AML with t(8;21)(q22;q22), *(AML1-ETO);* AML with abnormal bone marrow eosinophils and inv(16)(p13q22) or t(16;16)(p13;q22), *(CBFB-MYH11);* acute promyelocytic leukemia (APL) with t(15;17)(q22;q21), *(PML-RARA),* and variants; and AML with 11q23 *(MLL)* abnormalities. It has been estimated that the t(8;21), t(15;17), inv(16), and *MLL* translocations are present in 12%, 7%, 12%, and 7% of cases of pediatric AML, respectively.[602,604] However, these frequencies are inexact, with another study using standard cytogenetic analyses finding *MLL* translocations in approximately 18% of cases.[605] Furthermore, other characteristic recurrent molecular cytogenetic aberrations are observed.

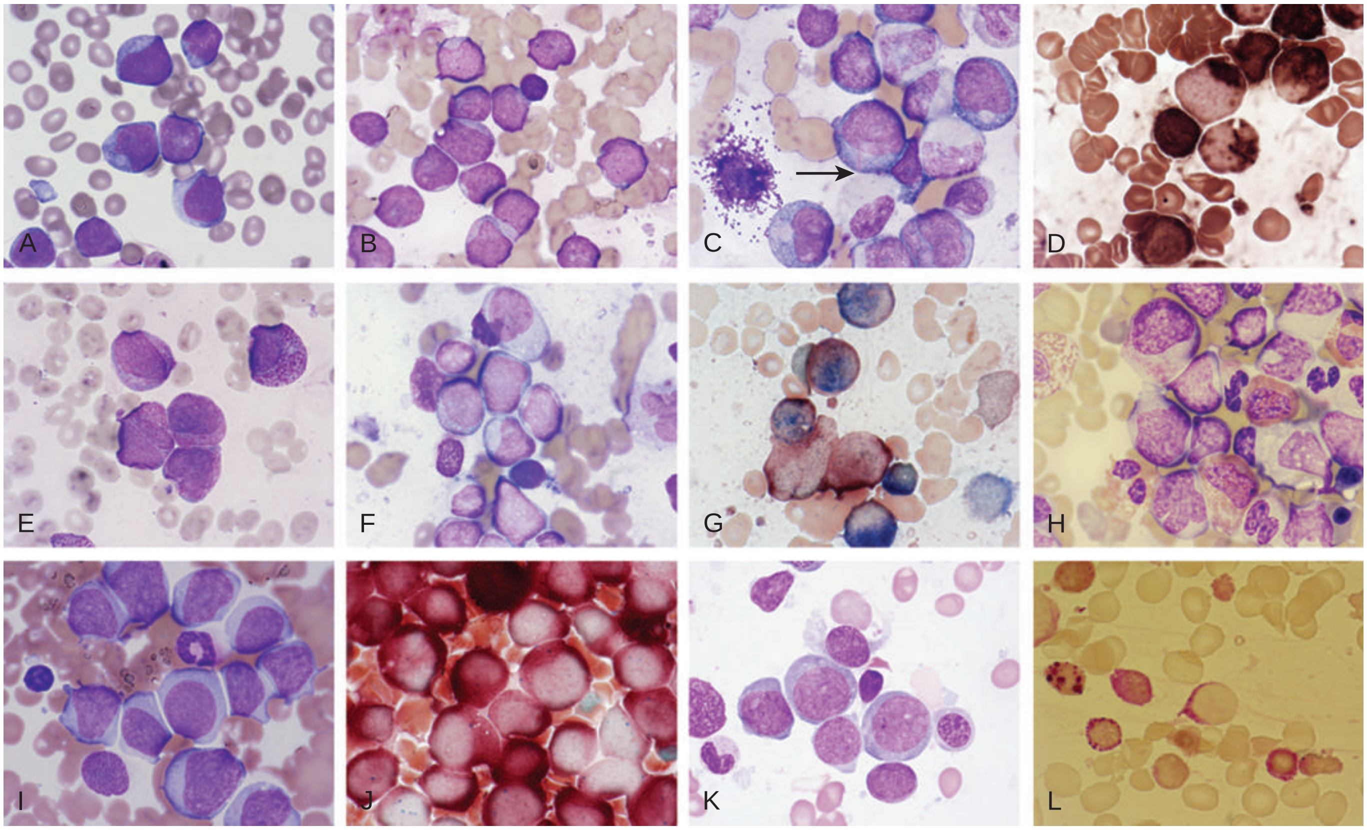

Figure 45-37 Major acute myeloid leukemia subtypes. M0 (**A**) and M1 (**B**) have minimal differentiation. **C,** M2 shows greater myeloid differentiation and may feature Auer rods *(arrow)* along with strong myeloperoxidase staining (**D**). **E,** M3 promyelocytic leukemia with typical coarse cytoplasmic granules. **F,** M4 myelomonocytic leukemia with staining for chloroacetate esterase *(blue)* in the myeloblasts, and nonspecific esterase *(brownish red)* in the monoblasts (**G**). **H,** M4eo with pronounced eosinophilic features. **I,** M5 monoblastic leukemia with staining for nonspecific esterase (**J**). **K,** M6 erythroleukemia with staining for periodic acid–Schiff (**L**). *(Courtesy Marybeth Helfrich, Children's Hospital of Philadelphia.)*

Although morphology no longer serves as the diagnostic gold standard for AML, the observation of a dyshesive, monotonous, immature cell population should trigger and guide further investigations by histochemical, immunophenotypic (including flow cytometric), and molecular cytogenetic methods. AML may exhibit morphologic features of any of the various hematopoietic progenitors or even of several simultaneously. The cytologic features, cytochemical staining pattern, and immunotype all assist in the subclassification of AML morphology by the FAB system, which recognizes the eight different subcategories (see Fig. 45-37) described here.

In FAB M0 AML there are more than 30% blasts with no or minimal features of myeloid differentiation. FAB M0 AML nuclei are generally large, with remarkably fine nuclear chromatin, prominent nucleoli, and high nuclear-to-cytoplasmic ratio.[606] The cytoplasm may exhibit focal granularity, and Sudan black reactivity is typical. Myeloperoxidase expression is inapparent by light microscopy but can be demonstrated by electron microscopy.

In FAB M1 AML, like in FAB M0, there are more than 30% blasts with minimal differentiation but, unlike in FAB M0, myeloperoxidase expression is readily demonstrable and accompanies Sudan black and chloracetate esterase positivity.

The diagnosis of FAB M2 AML is based on the observation of myeloblasts with some maturation, generally requiring more than 30% total blasts, with more than 10% of the blasts showing granulocytic differentiation. FAB M2 AML blasts also exhibit myeloperoxidase and chloracetate esterase staining. FAB M2 morphology is typical in AML with t(8;21).[607] Although the typical morphology of AML with inv(16)(p13;q22) is FAB M4eo, in one series a substantial fraction of pediatric AML with inv(16)(p13;q22) showed FAB M2 morphology.[608]

The classic FAB M3 APL has coarse cytoplasmic granules, the nuclear chromatin is less fine than in myeloblasts, and the nucleus often is eccentric. FAB M3v is an APL microgranular variant in which the cytoplasmic granules are finer than in classic FAB M3 APL, and the nuclei may have irregular contours, appearing reniform or folded. The genetic underpinnings, typically associated with t(15;17), are similar to FAB M3, but FAB M3v APL does not carry the risk for massive hemorrhage during chemotherapy induction that is associated with classic FAB M3 APL.

FAB M4 AML is acute myelomonocytic leukemia, which is composed of myeloblasts, monoblasts, and promonocytes. The monoblast has a substantially lower nuclear-to-cytoplasmic ratio than the myeloblast or promyelocyte; its nucleoli are more prominent and its cytoplasm is more abundant, with fine granularity and occasional vacuolation. Although the promonocyte has similar features, it shows a different cytoplasmic hue. Both monoblasts and promonocytes, whether in FAB M4 or FAB M5 AML, are nonspecific esterase positive. FAB M4 and FAB M5 AMLs also express chloracetate esterase, myeloperoxidase, and α-naphthol acetate, and some stain with PAS. FAB M4 and FAB M5 AMLs are typically, although not exclusively, associated with *MLL* gene translocations. FAB M4 AML with abnormal bone marrow eosinophils (FAB M4eo) is associated with inv(16)(p13;q22).

FAB M5 acute monocytic leukemias encompass two subcategories; one subcategory with no differentiation is FAB M5a (monoblastic leukemia), whereas the other with differentiation is FAB M5b. Monoblasts predominate in FAB M5a AML, but promonocytes predominate in the FAB M5b morphologic subtype.

FAB M6 AML is acute erythroid leukemia, which generally exhibits a predominance of erythroblasts but often also has a substantial myeloblast component. The erythroblast shows a high nuclear-to-cytoplasmic ratio and a condensed rounded nucleus. The cytoplasm is deeply basophilic and may contain vacuoles. FAB M6 cases express glycophorin and stain for PAS but not other cytochemical markers.

The FAB M7 category is acute megakaryoblastic leukemia (AMKL). FAB M7 AML may be associated with prominent marrow fibrosis, making aspiration difficult. The cells are pleomorphic (see Fig. 45-39) and the megakaryocytic nature may not be obvious by morphology alone. FAB M7 AMKL cells may express α-naphthol acetate. Expression of glycoprotein Ia, IIb, or IIIa or factor VIII can aid in the diagnosis of FAB M7 AMKL. As described in more detail later, AML in Down syndrome is AMKL; however, the t(1;22) is found in some non–Down syndrome cases.[609]

Major Chromosomal Translocations

t(8;21). The archetypal chromosomal translocation in FAB M2 AML is the t(8;21), which fuses the 5′ terminus of the *AML1 (RUNX1, CBFA2)* gene at chromosome band 21q22, with almost the entire *ETO* gene from chromosome band 8q22.[79] In one series, 82% of pediatric AML with this translocation had FAB M2 morphology.[607] These morphologic-cytogenetic correlates, although compelling, are imperfect. Therefore some classifications have taken account of cytogenetic abnormalities, thereby highlighting crucial biologic pathways and, in some cases, therapeutic targets.[603] The t(8;21) also is strongly associated with extramedullary granulocytic sarcoma presentations.[607,610] Leukemias with this translocation, which disrupt the *AML1* gene encoding the DNA-binding subunit of core binding factor, comprise one of the two subtypes of core binding factor leukemias. The AML1 fusion oncoprotein binds the non–DNA-binding subunit of core binding factor, CBFB, as does native AML1, but the fusion oncoprotein interacts with nuclear corepressors that inhibit AML1-mediated transcriptional activation through the deregulation of histone deacetylation.[79] The t(8:21) has been associated with a favorable prognosis in studies conducted by the Pediatric Oncology Group[611] and the Children's Cancer Group.[612] The t(8;21) has been associated with a mixed outcome in the experience of St. Jude Children's Research Hospital, but the treatment regimens did not specify repetitive high-dose cytarabine as did other regimens in which the t(8;21) was associated with a favorable prognosis.[607,612,613] Variant *AML1 (CBFA2)* translocations involving other partner genes have heterogeneous morphologic MDS and AML presentations, but these translocations occur primarily in adult leukemias and tend to be treatment related rather than to occur de novo.[614]

inv(16) and t(16;16). The second subtype of core binding factor AML has inversions or, less often, translocations fusing the *CBFB* gene encoding the non–DNA-binding subunit of CBF at chromosome band 16p13 to the *MYH11* gene at chromosome band 16q22.[615] The classic morphologic presentation of AMLs with inv(16) and t(16;16) in adults is myelomonocytic leukemia with eosinophilia (FAB M4eo)[616] but many pediatric cases present as FAB M2 or M4 AML, without eosinophilia.[608,617] RT-PCR analysis and FISH are particularly useful and important for the detection of this rearrangement.[618-621] Additionally, the leukemic blast cells may coexpress the CD2 T-cell surface antigen.[622] The inv(16) is leukemogenic via a mechanism of dominant transcriptional repression of AML1-regulated genes, so that the pathways involved and the biologic consequences are similar to those resulting from the t(8;21).[79] The outcome associated with this aberration is also favorable in several pediatric series, similar to the t(8;21).[623] In one large study of adults and children, the outcomes were comparable in patients undergoing allotransplantation and receiving high-dose or low-dose cytarabine, and the outcome was better in the younger patients.[624] Pediatric studies have found that current regimens incorporating intensive high-dose cytarabine into postremission treatment are associated with event-free survival rates of approximately 70% or higher.[605,612]

t(15;17). The t(15;17) fusing the *PML* and *RARA* genes at chromosome bands 15q22 and 17q21, respectively, is associated with FAB M3 APL.[625,626] The t(15;17) and variant translocations associated with APL disrupt the function of the retinoic acid receptor α (RARα), also called the RARA protein, which is a ligand-dependent transcription factor important in myeloid differentiation. The RARα protein forms a heterodimer with another ligand-dependent protein, retinoic X receptor protein (RXR). The natural ligand of RARα is all-*trans*-retinoic acid (ATRA), whereas RXR is responsive to ATRA or 9-*cis*-retinoic acid.[625] In the presence of ligand, the heterodimeric complex interacts with transcriptional co-activators to induce myeloid differentiation. In contrast, the molecular pathogenesis of APL involves the aberrant recruitment of transcriptional co-repressors and the histone deacetylase complex to RARα target genes. Notably, the first molecularly targeted agent ever to be implemented for antileukemia treatment was ATRA. Variant translocations fuse *RARA* with partner genes other than *PML,* including *NPM, NUMA1 (NuMA), STAT5b, PRKAR1A,* and *ZBTB16 (PLZF).*[625,627-630] The

PRKAR1A-RARA fusion was first identified by *RARA* FISH analysis in an ATRA-sensitive adult with APL who had normal cytogenetics by conventional karyotype analysis.[630] *PRKAR1A* encodes the regulatory subunit type 1α of cyclic adenosine monophosphate–dependent protein kinase,[630] and the karyotypically cryptic nature of the translocation highlights the importance of molecular cytogenetic testing. APLs with *PLZF-RARA* translocation are insensitive to ATRA, whereas those with the other *RARA* fusion types are ATRA responsive.[625]

Mixed-Lineage Leukemia* (MLL) *Gene Translocations. In contrast to ALL, in which *MLL* partner genes are limited and *AF4* is the most common, the partner genes are much more diverse in AML.[631] Nonetheless, *MLL* partner genes in ALL and AML, and in de novo and treatment-related leukemias, are at least partially overlapping. Many MLL partner proteins have structural motifs of nuclear transcription factors,[15,132,506] transcriptional regulatory proteins,[632] or other nuclear proteins.[633-635] Others are cytoplasmic proteins or cell membrane proteins.[132,518,636-642] *MLL* also undergoes self-fusion in a type of rearrangement termed *partial tandem duplication;* therefore in AML, MLL itself is an MLL partner protein.[45,643,644] As in ALL, cDNA panhandle PCR analysis has been applied to detect novel and rare partner genes of *MLL* and covert *MLL* rearrangements in AML.[645-647] There is no obvious functional relationship between the many partner genes of *MLL* but some are members of the same gene families.[518,638-640,648,649] It has been suggested that the nuclear partner proteins mediate transcriptional activation[132,649,650] and that cytoplasmic partner proteins cause forced MLL dimerization or oligomerization.[651] Several MLL partner proteins also interact with one another.[652] Fusion proteins from the der(11) chromosome, which retain the AT hook, SNL, and MT domains of MLL but replace the MLL PHD, transactivation, and SET domains with the carboxyl partner protein, transform hematopoietic progenitors and cause leukemia in mice.[653,654] In murine models, MLL fusion proteins constitutively activate *Hoxa9,* and *Hoxa9* activation is essential for leukemogenesis with some MLL fusion proteins (e.g., MLL-ENL).[515] However, altered *Hox* expression is not essential for leukemogenesis with other MLL fusion proteins, including MLL-AF9 and MLL-GAS7.[654,655]

As described earlier, balanced *MLL* gene translocations are the primary molecular aberrations underlying most cases of acute leukemia in infants.[503] AML is more common than ALL in neonates, unlike during the rest of infancy and childhood.[134,656] It has been estimated that *MLL* translocations are present in half of all ALLs and AMLs diagnosed during the neonatal period.[134] *MLL* translocations also comprise 5% to 10% of acquired chromosomal rearrangements in childhood AML.[657] The particular partner gene fused to *MLL* affects cell lineage and differentiation features, which are reflected in the immunophenotype. *MLL* translocations in AML are often associated with myelomonocytic and monoblastic features.[133] Leukemias with *MLL* translocations can also present as treatment-associated myelodysplastic syndrome or AML[658,659]; this is particularly characteristic of cases with t(11;16) fusing *MLL* with *CBP* (CREB binding protein).[632,660-662] Unlike in ALL, the presence of an *MLL* translocation is not an independent prognostic factor in pediatric AML with current treatment. However, in some series, the *MLL-MLLT3 (AF9)* fusion resulting from t(9;11) has been associated with a more favorable outcome than other *MLL* translocations[617] (e.g., *MLL-MLLT10 [ALF10]*).[663]

Certain clinical and laboratory features are associated with the archetypal neonatal FAB M4 and FAB M5 leukemias with *MLL* translocations. These features include cutaneous nodules (leukemia cutis), petechiae, and ecchymoses, in addition to the hematologic abnormalities (hyperleukocytosis, anemia, thrombocytopenia) and CNS involvement.[134,656,664] Curiously, congenital *MLL*-rearranged AML may be present predominantly in the skin and not in the marrow (aleukemic leukemia cutis) and, on occasion, can undergo spontaneous remission.[664,665] In these situations, molecular analysis of bone marrow and skin biopsy material is warranted because of the propensity for progressive disease when a clonal *MLL* rearrangement is identified.[664,665]

As discussed earlier for infant ALL, the *MLL* translocations in many infant AMLs are in utero events.[518] In some cases, however, an in utero origin cannot be demonstrated, possibly because the clonotypic sequences of the translocations are present below the detection limit of the PCR assay.[666] The occasional stillbirth presentations[134] and the presentation of monoblastic AML with an *MLL-ELL* rearrangement as a granulocytic sarcoma diagnosed by prenatal ultrasonography[667] further substantiate that *MLL* translocations arise in utero in infant AML. However, latency to leukemia underscores that additional secondary alterations are important, and perhaps required, for the development of leukemia with an *MLL* translocation.[132]

t(8;16). The chromosome 16 rearrangement in t(8;16)(p11;p13) is in the same band (16p13) disrupted by inversions and translocations of the *MYH11* gene in M4Eo AML.[615,668,669] However, the 16p13.3 breakpoints in t(8;16) target a different gene, encoding the transcriptional coactivator CREB binding protein (CBP; CREBBP) at chromosome band 16p13.3, which is fused with the *MOZ (MYST3)* gene on chromosome 8.[670] The CBP protein contains RARA and CREB binding domains, a bromodomain, and E1A and transcription factor IIB (TFIIB) binding regions, whereas MOZ contains zinc finger motifs and a MYST acetyltransferase domain.[670-674] The *CBP-MOZ* fusion transcript encoded by the der(16) chromosome is not in-frame, whereas the *MOZ-CBP* transcript is believed to have transforming properties and clinical relevance.[670,675,676] MOZ-CBP tumorigenic mechanisms have been proposed to involve inhibition of AML1-mediated transcriptional activation.[677] The *MOZ-CBP* rearrangement is associated with a gene expression signature that includes *HOXA9, MEIS1,* and *FLT3* overexpression, similar to the gene expression profiles in AML with *MLL* translocations.[678] Notably, *CBP* is also an occasional fusion partner of *MLL* in MDS.[632,660-662] *CBP* oncogenic aberrations can be constitutional, as evidenced by the germline *CBP* point mutations, microdeletions, and translocations that underlie the Rubinstein-Taybi syndrome.[679-681]

The t(8;16) is associated with a prognostically unfavorable subset of FAB M4 and FAB M5 AMLs, other features of which include erythrophagocytosis and coagulopathy.[682,683] Therefore recognition of this AML subset is clinically important and can be accomplished by molecular cytogenetic detection of the rearrangement. Although a rare translocation, accounting for only approximately 2% of pediatric AML,[684] most AMLs with this translocation have occurred in infants and children.[670,683] The t(8;16) in neonatal AML, like translocations in several other AML subtypes, can be associated with leukemia cutis and spontaneous remission.[685,686]

A variant t(10;16) translocation fuses the *KAT6B (MORF)* gene at chromosome band 10q22 to *CBP* and was discovered in a case of childhood FAB M5a AML.[687] The MORF protein contains zinc fingers, nuclear localization signals, and a histone acetyltransfersase domain[687] and, similar to MOZ, contributes to chromatin remodeling.[674] Additional variant translocations result in fusion of *MOZ* with the *NCOA2 (TIF2)* or *EP300 (p300)* genes[688-690]; p300 is related structurally to CBP, and the MOZ-TIF2 oncoprotein recruits CBP. Therefore CBP-mediated oncogenic transcriptional regulatory functions appear crucial in the several translocation variants that compose this AML molecular cytogenetic subset.

t(6;9). The t(6;9) (p23;q34) translocation is a rare recurrent translocation in AML, primarily seen in adults, the clinical and molecular features of which include myelodysplasia, basophilia, a CD34– immunophenotype and *FLT3* mutations.[691-693] AML with t(6;9) in children and adolescents has had a poor prognosis.[684,695-696] The translocation occurs in various morphologic AML subtypes, including FAB M1, M2, and M4, and fuses the 5′ end of the *DEK* gene (chromosome 6) to the 3′ end of the *NUP214 (CAN)* gene (chromosome 9), creating a *DEK-CAN* oncogene.[697-699] The *DEK* gene product is a multimeric chromatin protein, regulated by CK2 kinase, which modifies DNA topology by the introduction of supercoils into closed circular DNA.[700,701] The *CAN* gene at chromosome band 9q34 (also called *CAIN,* because of its chromosomal proximity to *ABL*), encodes the nucleoporin protein NUP214 of the nuclear pore complex. DEK-CAN oncogenic roles in leukemogenesis involve a myeloid lineage-specific increase in protein translation, which occurs in conjunction with increased eIF4E translation initiation factor phosphorylation.[702] Leukemias with the *DEK-CAN* fusion may have oncogenic mechanisms in common with other AML subtypes, as is suggested by the observation that nucleoporin-specific FG repeats in the fusion oncoprotein can induce transcriptional activation by recruitment of the transcriptional coactivators CBP and p300. Reverse-transcriptase and real-time PCR methods have been helpful for AML monitoring in patients with this rearrangement, because the persistence of the fusion transcript identifies patients at risk for relapse.[703-705] A translocation variant resulting in the *SET-CAN* oncogenic fusion gene has been observed in AML of the FAB M0 subtype.[697]

NUP98 *Translocations.* The *NUP98* gene at chromosome band 11p15 encodes a nucleoporin protein that serves as a structural component of nuclear pore complex. The NUP98 protein is located on the nucleoplasmic side of the nuclear pore and provides a docking site for the export of mRNA between the nucleus and cytoplasm.[706,707] Various chromosomal translocations produce *NUP98* oncogenic fusions and, depending on exactly which partner gene is fused with *NUP98*, these translocations can be associated with de novo or treatment-related AML, ALL, or MDS.[706-726] Many of the *NUP98* partner genes encode homeobox transcription factors, but some of the partner genes, including *TOP1* and *TOP2B,* have more diverse functions.[708,717,723] Several *NUP98* fusions, such as those involving *NSD1*, *HOXD13,* and *PSIP1 (LEDGF),* are found in infant and pediatric de novo AML.[718,724,725] t(7;11)(p15;p15), which fuses *NUP98* with *HOXA9,* and t(10;11)(q23;p15), which fuses *NUP98* with *HHEX,* have been shown to shift the cellular distribution of NUP98 away from the nuclear pore complex and into intranuclear aggregation bodies.[711,719] Because of the substantial variety of *NUP98* partner genes, it is most feasible to detect these rearrangements using a general *NUP98* break-apart FISH strategy.[723,727] cDNA panhandle PCR assay has also been applied as a gene discovery tool to identify new partner genes in leukemias with *NUP98* translocations.[728]

Therapy-Related Acute Myeloid Leukemias and Myelodysplastic Syndromes

Therapy-related AMLs and MDS comprise a separate WHO AML subgroup[603] relevant to pediatrics; two major categories have been recognized. Therapy-related leukemias are of increasing concern in children, in whom survivorship—as a percentage of patients diagnosed with cancer—is greater than in the adult cancer population.[729] Therapy-related leukemia or MDS is also well-recognized as a long-term complication after autologous hematopoietic stem cell transplantation.[730-732] The two major categories of chemotherapies associated with leukemia and MDS are alkylating agents and TOP2 poisons. The forms of leukemia associated with these agents have distinctive molecular cytogenetic features, which can also be found in subsets of leukemia arising de novo.

All alkylating agents engender some risk for leukemia as a treatment complication, but the risk is variable, depending on the particular agent(s), cumulative dose, patient age, and superimposed effects of radiation therapy.[733-736] The latency period is variable, ranging from 2 to 12 years after exposure, but the peak incidence occurs at approximately 6 years.[737] The archetypal cytogenetic features in alkylating agent–related leukemias are complete or partial deletions of chromosomes 5 and 7 and complex, unbalanced, numeric and structural cytogenetic abnormalities.[738] The chromosome 7 aberrations are the most common cytogenetic events in leukemias after alkylating agent treatment.[739,740] Most cases with chromosome 7q deletions exhibit allelic loss of the chromosomal segment between bands 7q22 and 7q31 but, despite identification of various candidate genes in this genomic region, the exact tumor suppressor gene(s) have not been convincingly identified.[741-745] In treatment-associated MDS and AML lacking chromosome 5 aberrations, the monosomy 7 or del(7q) may be acquired by subclone evolution and accompanied by other key mutational aberrations, including t(3;21), *RAS* mutation, and CDKN2B promoter hypermethylation.[740]

Monosomy 5 and del(5q) are the next most common aberrations in alkylating agent–related MDS and AML. FISH analyses have revealed that the chromosome 5q abnormalities frequently are covert unbalanced translocations.[740] The chromosome 5q abnormalities arise as primary aberrations and not by subclone evolution, and additional aberrations in therapy-related MDS and AML with monosomy 5 or del(5q) can include monosomy 7 or del(7q), *TP53* mutations, and gene duplications, such as *MLL* segmental jumping translocations.[16,740,746] The critical genes targeted by 5q deletion have been difficult to pinpoint because of variable involvement of a large genomic region that encompasses chromosome bands 5q13 to 5q33.[739,747-753] Two recently implicated chromosome 5q31 candidate genes are *CTNNA1* encoding the α-catenin protein[754] and the *EGR1* gene,[755] although there have been several others.[739,747-753] Epigenetic dysregulation may also contribute to the pathogenesis, with transcriptional silencing in the retained nondeleted *CTNNA1* allele resulting from promoter methylation and histone deacetylation.[754]

A tumor suppressor gene, *RPS14,* has been identified as the target of 5q– in the syndrome of refractory anemia, in which there is preservation of megakaryopoiesis and myelopoiesis,[756] but the role of *RPS14* in therapy-related MDS and AML remains to be determined. This gene encodes a ribosomal protein required for processing of 18S pre-rRNA.[756] The strategy of screening normal human CD34+ cells with short hairpin RNAs (shRNAs) against various genes in the minimal 5q– deletion region has revealed that *RPS14* silencing causes erythroid maturation block and increased apoptosis in differentiating erythroid cells, similar to the increased apoptosis observed in MDS.[756] Furthermore, lentiviral RPS14 expression restored erythroid differentiation in bone marrow cells from patients with 5q– refractory anemia syndrome.[756] These insights underscore the role of ribosomal genes in anemia, given that other ribosomal genes, *RPS19* and *RPS24,* contribute to Diamond-Blackfan anemia.

Most AMLs developing after autologous hematopoietic stem cell transplantation have complex numeric and structural karyotypic aberrations, including losses of chromosomes 5 and 7; these are also features of AML arising after exposure to alkylating agents.[732,757-759] The secondary AMLs can occur early after transplantation, and the cytogenetic aberrations in these treatment-associated leukemias are often demonstrable in pretransplantation specimens, suggesting that the genotoxic damage results from the prior therapy.[757,760] On the other hand, such cytogenetic aberrations are not demonstrable in the peripheral blood stem cell autografts.[761]

Therapy-related leukemias can be caused by exposure to various chemotherapeutic TOP2 poisons, including epipodophyllotoxins and anthracyclines, the anthracenedione mitoxantrone, and the TOP1/TOP2 interacting agent dactinomycin.[63] Balanced translocations, often involving the *MLL* gene,[562] are the most typical molecular alterations in leukemias related to TOP2 poisons. The typical latency is 2 to 2½ years after chemotherapy exposure,[658,762] although more protracted latencies of up to 10 years have been described.[645,763] A particularly high risk has been reported in association with high cumulative doses of etoposide and anthracyclines,[764] but other studies have not found a correlation between etoposide cumulative dose and secondary leukemia risk.[765] Intermittent weekly or twice-weekly etoposide dose schedules, and semicontinuous schedules, have also been associated with increased risk for secondary AML.[764,765] The *MLL* translocations in therapy-related AML (as is the case in de novo AML) are often associated with myelomonocytic and monoblastic morphology.[766,767] Other translocations in therapy-related MDS and AML include t(8;21) and its variants,[614,768-777] t(15;17),[778] inv(16) and t(16;16),[762,779-782] t(8;16),[783,784] t(9;22),[783] and various translocations involving the *NUP98* gene at chromosome band 11p15.[708,709,711,785-788]

Treatment-related MDS/AML can present as bizarre and highly abnormal morphology in some cases (Fig. 45-38) but, in others, can be insidious and challenging to diagnose, particularly in patients actively receiving treatment, in whom the hematologic features of cytopenia and monocytosis can be indistinguishable from ordinary side effects of chemotherapy and recovery of the marrow. Additionally, some patients with treatment-related MDS and AML, particularly in the early stages, have no obvious peripheral blood cell abnormalities at all.[51,637] Therefore one front-line pediatric neuroblastoma treatment protocol has specified routine bone marrow surveillance every 3 to 6 months, not only for neuroblastoma relapse but also for leukemia-associated aberrations.[51] In addition to the insidious nature of the clinical presentations, the spectrum of known molecular cytogenetic abnormalities associated with therapy-related MDS and AML is constantly increasing and is already very large, creating the yet-unmet need for broad molecular cytogenetic screening

methods with which to monitor high-risk patients. For example, even though there are few data on patients observed in this manner, it seems that most of the protean *MLL* translocations emerging during treatment, which involve many different partner genes, are harbingers of MDS or AML.[51,637,789] An *MLL-FRYL* translocation that was traced prospectively by molecular cytogenetic testing (FISH, panhandle PCR assay) caused clonal replacement of the bone marrow without affecting differentiation, only after a long latency culminated in clear-cut therapy-related MDS.[51] However, clinical progression is apparently not inevitable because, in one patient, the morphologically normal clone harboring an *MLL-ARHGEF17* translocation gradually regressed and neither leukemia nor MDS ensued.[790]

Additional challenges for molecular characterization result from the variable locations of *MLL* translocation breakpoints, which can be within or outside a breakpoint hot spot region.[45,47,51,63,121,134,139,155,463,465-470,632,647,791,792] Secondary myeloid disorders are particularly challenging to diagnose in patients previously diagnosed with AML, for example, the *MOZ* oncogenic rearrangement resulting from a novel t(2;8)(p23;p11.2) translocation in treatment-related MDS after AML in a pediatric patient.[793]

Clinically, the molecular cytogenetic features of the therapy-related leukemias are important prognostic factors. Most cases, except those with favorable translocations—t(8;21), inv(16), t(15;17)—are resistant to current treatment strategies, but intensive regimens, including hematopoietic stem cell transplantation, have been more successful. Prognosis is affected further by the reduced tolerance to additional intensive antileukemia therapy after primary cancer treatment.[794] Nonetheless, just as in the de novo leukemias, additional targeted therapy options are emerging from an understanding of the molecular cytogenetic aberrations in these challenging disorders.

Myelodysplasia and Myeloproliferative Diseases

Myelodysplasia and myeloproliferative diseases comprise a very small fraction (<10%) of all hematologic malignancies in children. Incomplete coverage of various unique features of pediatric MDS and myeloproliferative diseases in the current WHO classification system has led to the development of diagnostic guidelines for MDS and myeloproliferative categories applicable specifically to children.[795] To fulfill minimal diagnostic criteria for MDS, at least two of the following four features are required: (1) sustained unexplained cytopenia; (2) bi-lineage morphologic myelodysplasia; (3) acquired clonal hematopoietic cell cytogenetic abnormality; and (4) 5% or more blasts in the marrow.[795] In contrast to AML, which is defined by a bone marrow blast threshold of 20% and aberrant differentiation, and to MDS, myeloproliferative disorders are characterized by expansion of one or more hematopoietic lineages but retained differentiation.[795,796] Three major categories of MDS and myeloproliferative diseases are applicable to children: (1) a group of myelodysplastic-myeloproliferative disorders comprising primarily juvenile myelomonocytic leukemia (JMML); (2) myeloid leukemia of Down syndrome; and (3) MDS.[795]

Juvenile Myelomonocytic Leukemia. The constellation of hepatosplenomegaly, lymphadenopathy, pallor, and rash, especially in children younger than 3 years old, comprises the clinical features of JMML, the diagnostic criteria for which include peripheral monocytosis, absence of the *BCR-ABL* rearrangement, less than 20% blasts in the bone marrow, and at least two of the following: increased fetal hemoglobin, circulating myeloid precursors (Fig. 45-39), a white blood cell count more than 10 × 10^9/L, presence of a clonal cytogenetic abnormality, and in vitro hypersensitivity of myeloid precursors to granulocyte-macrophage colony-stimulating factor (GM-CSF).[796] Children with neurofibromatosis type 1 (NF1) or Noonan syndrome are predisposed to JMML. Notably, several of the key molecular abnormalities contributing to JMML pathogenesis result in RAS signaling pathway hyperactivation.

Many hematopoietic growth factors transduce signals from the cell surface to the nucleus through RAS family proteins, which regulate cellular proliferation and differentiation by cycling between active guanosine triphosphate (GTP)-bound and inactive guanosine diphosphate

(GDP)-bound states.[797,798] Somatic mutations in *RAS* oncogenes are one mechanism of RAS pathway activation and are found in 20% to 30% of JMMLs,[798,799] often involving *KRAS* or *NRAS* at codons 12, 13, or 61. Some cases of *RAS*-mutant JMML undergo spontaneous regression,[800] whereas *NRAS*-mutant JMML can progress with loss of the remaining normal *NRAS* allele.[801] Monosomy 7 is also found in some cases of JMML with *RAS* oncogene mutations.[802]

The *NF1* tumor suppressor gene product, neurofibromin, is a GTPase activating protein that accelerates GTP hydrolysis on RAS proteins.[803] Germline mutations in the *NF1* gene, often with accompanying loss of the normal *NF1* allele, result in elevated levels of GTP-bound RAS. Thus germline *NF1* mutations comprise an alternative mechanism for hyperactivating the RAS signaling pathway, predisposing to JMML.[803,804] LOH at the *NF1* locus is observed in approximately 50% of JMML arising in patients with NF1.[803] In NF1 kindreds, JMML is seen particularly in boys with maternal transmission of the mutant *NF1* allele.[805] Additional mutations in the *NF1* gene, with or without LOH, occur in sporadic JMML that is not associated with the NF1 syndrome.[806] In some of these cases, the *NF1* mutations are germline, with JMML being the presenting feature of the NF1 syndrome. Overall, it is estimated that *NF1* mutations are present in approximately 30% of all JMMLs.[806] Monosomy 7 occurs in addition to *NF1* mutation in some JMMLs.[803] However, *NF1* and *RAS* mutations in JMMLs are mutually exclusive.[806]

Noonan syndrome is an autosomal dominant disorder associated with germline mutations in the *PTPN11 (SHP2)* gene in approximately 50% of cases and is characterized by JMML, facial dysmorphology, short stature, and cardiac defects.[807] The *PTPN11* gene product, SHP2 phosphatase, regulates RAS-MAPK pathway signaling but is inactive in its baseline state.[808,809] *PTPN11* mutations in Noonan syndrome result in SHP2 activation and, consequently, hyperactivation of RAS-MAPK signaling.[808] In pediatric patients without Noonan syndrome, *PTPN11* somatic mutations can be found in sporadic cases of JMML, MDS, AML (particularly the FAB M5 subtype), and B-cell lineage ALL.[810-814] Somatically acquired *PTPN11* mutations are present in 30% to 35% of de novo JMML.[811,814] Generally, the types of *PTPN11* mutations occurring as somatic events in nonsyndromic cases are more strongly activating than the germline *PTPN11* mutations in patients with Noonan syndrome.[796,815] The fact that *PTPN11* mutations are less strongly activating in patients with Noonan syndrome might explain why syndromic JMML is associated with less severe hematologic abnormalities and can resolve spontaneously.[796,811] Thus dysregulation of the RAS signaling pathway by *RAS, NF1,* or *PTPN11* mutations is instrumental to the aberrant cell growth and differentiation in JMML, and these three mechanisms of RAS dysregulation are usually mutually exclusive.[814]

The myeloproliferative disorder known as monosomy 7 syndrome has clinical overlap with JMML and is characterized by myelodysplasia, thrombocytopenia, anemia, and hepatosplenomegaly.[816] However, this disorder is not included in the more recent classification system for pediatric myelodysplastic and myeloproliferative diseases.[795]

Chronic Myelomonocytic Leukemia. Chronic myelomonocytic leukemia (CMML) is a clonal bone marrow stem cell disorder characterized by monocytosis, myelodysplasia, and absence of *BCR-ABL* fusion.[41,603] t(5;12)(q33;p13), which generates the *TEL-PDGFRB* fusion product, is a recurring but rare rearrangement in CMML.[603] The case in which the fusion transcript was first described occurred in an adolescent patient.[817] t(5;12) is associated with eosinophilia and progression to AML on acquisition of additional cytogenetic changes.[817] However, only secondary and not de novo CMML is included as a diagnostic category in the pediatric adaptation of the WHO classification of myelodysplastic and myeloproliferative diseases.[795]

Transient Abnormal Myelopoiesis and Acute Megakaryoblastic Leukemia of Down Syndrome. Ten to 20 percent of neonates with Down syndrome are affected with transient abnormal myelopoiesis (TAM), and 20% to 30% of TAM will progress to AMKL by 4 years of age (see Fig. 45-39).[818-820] Several laboratories have identified truncating *GATA1* point mutations as in utero mutational oncogenic events that initiate both TAM and AMKL.[818,821] GATA1 is a hematopoietic transcription factor that, via interactions with the FOG1 cofactor and GATA2, regulates erythroid and megakaryocyte maturation.[818] However, whereas the *GATA1* mutation is sufficient for TAM, postnatal secondary changes such as *TP53* mutation and/or trisomy 8 are required for subsequent clonal expansion, a prerequisite for disease progression to AMKL.[822] In many cases of TAM, however, there is no disease progression because the clone with *GATA1* mutation is ultimately extinguished in the absence of requisite secondary alterations.[818] The TAM and AMKL in Down syndrome have distinct gene expression profiles.[819]

Several chromosome 21 genes, including *CBS* (cystathionine beta-synthase), at band 21q22 may contribute to the unique forms of leukemogenesis in Down syndrome.[823] The *CBS* gene is overexpressed, above and beyond the levels predicted based on the trisomy 21 increased gene dosage. This upregulation seems to result from mechanisms involving transcriptional upregulation through the *CBS* promoter.[823] Consequences of *CBS* overexpression include reduced levels of plasma homocysteine, methionine, *S*-adenosylmethionine and *S*-adenosylhomocysteine, resulting in altered CpG methylation and consequent dysregulation of gene expression. Other effects include perturbed folate metabolism and genetic instability (increased DNA mutations), which may predispose to accumulation of the secondary genetic mutations in AMKL.[823] Another consequence of *CBS* overexpression is increased cytarabine sensitivity,[823] which contributes to increased treatment-related toxicities and to the more favorable outcome associated with myeloid leukemia of Down syndrome.[824]

t(1;22)(p13;q13), which fuses *RBM15 (OTT)* and *MLK1 (MAL),* is associated with non–Down syndrome

AMKL, another distinct form of AMKL peculiar to neonates.[134,503,825]

Myelodysplastic Syndrome. The three MDS morphologic subtypes of greatest relevance in pediatrics are refractory cytopenia, refractory anemia with excess blasts (RAEB), and RAEB in transformation (RAEB-T).[796] Monosomy 7 or del(7q) occurs in approximately 40% of cases and is the most commonly acquired cytogenetic aberration in pediatric MDS.[826] In cases of refractory cytopenia, monosomy 7 is associated with disease progression and poor outcome.[795,827] Similarly, monosomy 7, with or without other cytogenetic abnormalities, is a frequent finding in RAEB-T.[826] Despite the generally poor prognosis of −7/del(7q) in MDS, spontaneous and durable hematologic remissions have been described in some children diagnosed with MDS characterized by this cytogenetic feature.[828] Rarely, MDS with monosomy 7 is familial and observed in siblings.[805,829] In one study of refractory anemia of childhood, which is a form of refractory cytopenia, cytogenetic analyses have demonstrated monosomy 7 in 49% of cases, whereas trisomy 8 was the next most common abnormality, found in 9% of cases.[827] The 5q− syndrome associated with an indolent refractory anemia but with preservation of megakaryopoiesis and myelopoiesis[756] has not been described in children.[795] FISH analysis with chromosome-specific probes in combination with immunophenotyping has enabled characterization of the cell lineages affected by the clonal aberrations in MDS[830] as well as evaluation of the lineages affected by MDS clonal expansion.[831] MDS secondary to prior therapy has been discussed earlier. As is true for adults,[734] pediatric patients with MDS secondary to cytotoxic therapies (see earlier) often have chromosome 5 and 7 abnormalities.[832] Constitutional disorders associated with congenital bone marrow failure syndromes and acquired aplastic anemia are included in the differential diagnosis of MDS in children.[795]

Other Clinically Important Genomic Aberrations in Myeloid Disorders

It has been proposed that in addition to the major chromosomal aberrations that underlie the various AML morphologic subtypes, cooperating mutations affecting proliferation and differentiation are essential in AML pathogenesis[503] and may affect prognosis and treatment. The balanced chromosomal translocations that disrupt major hematopoietic transcription factor genes are generally regarded as the primary molecular alterations in the associated AML morphologic subsets. Translocations that disrupt major hematopoietic transcription factor genes generally alter differentiation,[503] whereas additional aberrations, including kinase or RAS-RAF pathway gene mutations, often contribute to hyperproliferative behavior.

***FLT3* Alterations.** Although less common than in adult AML, *FLT3* mutations are nonetheless found in a considerable minority of pediatric AML cases, with juxtamembrane region ITD and activation loop point mutations identified in 12% to 15% and 7% to 9% of pediatric cases, respectively.[565,833,834] Indeed, *FLT3* mutations might represent the most frequently occurring molecular abnormalities in AML. *FLT3* mutations are common in pediatric AML with *MLL* translocations; 23% of *MLL*-rearranged AML in one large series harbored either *FLT3*-ITD or kinase domain mutations.[565] Also, *FLT3* mutations are particularly common in AMLs with normal karyotypes, in which they are demonstrable in up to 60% of cases.[565] Another subset of AML features autocrine FLT3 activation caused by the expression of FLT3 ligand, resulting in constitutive FLT3 phosphorylation and signaling.[834] *FLT3*-ITD mutations in pediatric AML are associated with poor outcomes, similar to those in adult cases.[834-836] An increased *FLT3*-ITD allelic ratio is associated with relapse, and molecular diagnostic tests have been developed to detect *FLT3* mutations and quantify the *FLT3*-ITD allelic ratio.[837,838] *FLT3*-ITD mutations occur in approximately 30% of childhood APL.[837] *FLT3*-ITD mutations, although common in de novo AML, are infrequent in treatment-related cases, as reported in an adult series.[839]

***KIT* Mutations.** Mutations in the *KIT* receptor tyrosine kinase gene are also common in pediatric AML and occur most often in cases with t(8;21) or inv(16), which disrupt DNA or non–DNA-binding subunits of CBF.[840] The *KIT* mutations are associated with constitutive, ligand-independent activation of the KIT protein. One recent study has estimated that 37% of all AML in children with either t(8;21) or inv(16) harbor *KIT* mutations. *KIT* mutations do not affect prognosis but are nonetheless significant because preclinical studies have indicated that AML with *KIT* mutations are sensitive to imatinib mesylate and FLT3 inhibition.[840]

***RAS* Mutations.** It has long been recognized that the *RAS* oncogene family members can be activated by mutations in myeloid neoplasms,[841] although these mutations do not usually have prognostic relevance.[840] Mutations of *NRAS* or *KRAS* codons 12, 13, or 16 have been described in approximately 20% of pediatric AMLs with *MLL* translocation[842] and in approximately 30% of pediatric AMLs with t(8;21) or inv(16).[840] *RAS* mutations are also found in about one third of MDS with monosomy 7.[843] In secondary AML, *RAS* mutations are less common than in de novo disease[844,845] but are seen more often in alkylating agent–related cases, especially cases with monosomy 7, than in AML arising after exposure to TOP2 poisons. Additional evidence of RAS pathway oncogenic roles is seen in the germline *RAF1* mutations in adult therapy-related AML.[846] RAF1 is activated by RAS binding and participates in RAS signaling.

***PTPN11* Mutations.** The RAS/RAF/MEK/ERK signaling pathway can also be activated by mutations in the SHP2 phosphatase gene, *PTPN11*. Although somatic *PTPN11* mutations are uncommon, and occur in only approximately 4% of childhood AMLs overall, *PTPN11* mutations have a predilection for the FAB M5 morphologic subtype, in which they are found in approximately 18% of cases.[813]

PI3K/AKT/mTOR Pathway Aberrations. The PI3K/AKT/mTOR pathway is a signaling pathway that promotes cell proliferation and survival in leukemia. In adults, constitutive AKT activation, leading to downstream mTOR activation, contributes to the progression of MDS to AML.[847,848]

PTEN is a tumor suppressor protein that inhibits the PI3K/AKT/mTOR signaling pathway. Although *PTEN* gene mutations and LOH are uncommon in AML, aberrant *PTEN* mRNA splicing has been demonstrated, primarily in adult AML.[849] Constitutive PTEN phosphorylation, which results in PTEN inactivation, may contribute to AML,[850,851] whereas reduced PTEN expression may be important in MDS progression.[847] These oncogenic mechanisms may impede normal PTEN functions, which include not only attenuation of PI3K survival signaling but also promotion of hematopoietic stem cell quiescence and preservation of the self-renewal capacity of the hematopoietic stem cell compartment.[852]

***TP53* Mutations.** TP53 is a crucial cell cycle regulatory tumor suppressor protein that senses and responds to DNA damage by regulation of the G1-S cell cycle checkpoint. *TP53* mutations are features of alkylating agent–related leukemias in adults and children.[16,746,845,853] In contrast to *RAS* mutations, *TP53* mutations are more common in therapy-related than de novo cases.[845] Segmental jumping translocations are chromosomal abnormalities in which multiple copies of various oncogenes are dispersed extrachromosomally and throughout the genome.[16] Gene amplification accompanies loss of wild-type TP53 after exposure to genotoxic agents, and *TP53* mutations and *MLL* segmental jumping translocations are strongly associated, with both occurring after alkylating agent treatment.[746] The *TP53* mutations may be of germline origin.[16,854] Similarly, *TP53* gene mutations are associated with *AML1* gene amplification or duplication in MDS and AML after alkylating agent treatment.[855] *TP53* mutations occur in de novo AML in patients affected with the Li-Fraumeni syndrome.[67,856]

***NPM1* (Nucleophosmin) Mutations.** The *NPM1* gene encodes a nucleolar shuttle protein with multiple functions in protein trafficking, preribosomal assembly, and ARF-TP53 pathway regulation.[857,858] t(5;17), a variant translocation in APL, involves fusion of the *NPM1* gene to *RARA*,[628] and *NPM1* is fused to *ALK* in a subset of anaplastic large cell lymphomas.[859] Identification of *NPM1* point mutations in adult AML without karyotypic abnormalities has led to the recent analysis and discovery of *NPM1* mutations in childhood AML. The mutations cause loss of nucleolar localization with accumulation of nucleophosmin in the cytoplasm. Leukemic cells with *NPM1* mutations have a particular gene expression signature of *HOXB2, HOXB3, HOXB6,* and *HOXD4* upregulation.[860] In contrast to adult AML, in which *NPM1* mutations are present in 25% to 35% of cases, and even in up to 60% of cases with a normal karyotype, the frequency of *NPM1* mutations in pediatric AML is only 7% to 8%. Similar to adult AML, however, *NPM1* mutations are concentrated in patients with normal cytogenetics and, in the absence of *FLT3*-ITD mutations, *NPM1* mutations are associated with an especially good prognosis.[857,858] *NPM1* mutations in AML are more common in older than younger children and in girls than boys.[857] In addition, *NPM1* mutations are significant because they may facilitate risk stratification and allow for minimal residual disease detection in cases in which no other molecular cytogenetic markers are available.[858]

Monosomy 7 and del(7q). Monosomy 7 or del(7q) occurs with or without other cytogenetic aberrations in only 4% to 5% of pediatric AMLs but in 40% of pediatric MDSs.[826] Because of the infrequency of these aberrations, an international retrospective study was conducted to characterize −7 and del(7q) in pediatric AML and MDS. del(7q) is more common than −7 in AML cases with favorable cytogenetic features, such as t(8;21), inv(16), t(15;17), or t(9;11), whereas −7 is more common in cases with inv(3), t(9;22), i(17q), or +21. Further subgroup analysis, which was enabled by the size of the study, has demonstrated that −7 is associated with inferior survival compared with del(7q) and that survival is worse in the del(7q) subgroup without other favorable cytogenetic features compared with the del(7q) group having other favorable cytogenetic features.[826]

***IDH1* and *IDH2* Mutations.** A novel type of mutations in AML affects the isocitrate dehydrogenase 1 *(IDH1)* and isocitrate dehydrogenase 2 *(IDH2)* genes, which encode the metabolic enzymes responsible for conversion of isocitrate to α-ketoglutarate.[861] These mutations result in the production of an aberrant oncometabolite 2-hydroxyglutarate. They are associated with a global pattern of DNA hypermethylation because of the dependence of *TET2* on α-ketoglutarate and the resultant impaired oxidation of 5mC by the TET2 enzyme.[862] Somatic *IDH1* and *IDH2* mutations characterize15% to 23% of cases of adult AML, and they occur in AML cases in which there are few other molecular cytogenetic abnormalities.[861,863] A genomic classifier in adult AML has suggested that the co-occurrence of *IDH1* or *IDH2* mutation with *NPM* mutation in absence of the *FLT3*-ITD predicts a favorable prognosis.[863] However, in pediatric AML, *IDH1* and *IDH2* mutations appear to be much less common. In studies conducted by the Children's Oncology Group, there were no *IDH1* mutations[864] and *IDH2* mutations were detected in 2.2% of cases, in which accompanying t(8;21), MLL translocation, or *NPM* mutation was detected.[865] In another study, two *IDH1* and one *IDH2* mutations were detected in 206 cases of pediatric AML. Interestingly, both *IDH1* mutations occurred in cases with MLL–partial tandem duplication of FAB M0 morphology.[866]

***TET2* Mutations.** The TET2 DNA methylase enzyme catalyzes the oxidation of 5mC to 5-hydroxymethylcytosine (5hmC) in a reaction that is dependent on α-ketoglutarate.[862] Circos maps have suggested that *IDH1* or *IDH2* mutations and *TET2* mutations in adult AML are mutually exclusive.[862] Both *IDH1* and *IDH2* mutations as well as *TET2* mutations are associated with impaired hematopoietic differentiation programs.[862] *TET2* mutations have been reported in 6% of pediatric AML, a frequency more similar to that in adult AML.[863,865] In a second pediatric study, their frequency was only 1.7% and they were found with *FLT3*-TKD, *FLT3*-ITD plus *CEBPα*, and *KRAS* plus *WT1* mutations.[866] *TET2* mutations in adult AML are most often associated with an intermediate prognosis.[862] The results of the latter pediatric study, which also examined the mutation frequency in *ASXL1* (1.1%) and *DNMT3* (0), altogether indicate that the occurrence of mutations in genes whose products regulate DNA methylation and histone modification is less in pediatric AML than in AML in adults, but also that, when present, there are more accompanying molecular cytogenetic aberrations in the pediatric cases.[866]

MicroRNA Abnormalities

Levels of a particular microRNA, miR-223, are low in AML with the t(8;21) translocation.[597] The underlying mechanism was shown to involve epigenetic transcriptional silencing of miR-223 by the AML1-ETO fusion oncoprotein through the recruitment of several chromatin-remodeling enzymes, including DNA methyltransferases and HDAC1 to the pre–miR-223 gene.[867] The ages of the patients studied were not specified (they were presumably adults), but t(8;21) is a feature of AML in adult and pediatric patients.

CONCLUSION

It is now possible to characterize and understand the cytogenetic and molecular pathobiology of the many forms of pediatric cancer in unprecedented detail using a panoply of approaches starting with decades-old conventional cytogenetic analysis of larger chromosomal aberrations that have withstood the test of time, advanced genomic methods reliant on the many derivatives of recombinant DNA technologies that followed later on and, now, next-generation sequencing of the whole transcriptome, genome, and epigenome, not only globally but within single cells. The ascertainment of cancer gene alterations and the cytogenetic and molecular subclassification of the many pediatric cancers outlined in this chapter is significant because the disruption of particular oncogenic pathways has prognostic and therapeutic relevance and is leading to the discovery of therapeutic targets that provide opportunities for new directed treatments.

CHAPTER OUTLINE

CHEMOTHERAPEUTIC AGENTS
CLINICAL APPLICATION OF CHEMOTHERAPY
CHEMOTHERAPY IN CHILDREN
PHARMACOKINETIC CHANGES DURING CHILDHOOD
Absorption
Volume of Distribution
Hepatic Metabolism
Renal and Hepatic Excretion
Influence of Underlying Disease on Metabolism
Unique Drug Effects in Pediatric Patients
DRUG INTERACTIONS
Combination Chemotherapy
Coadministration of Non-Anticancer Drugs
Coadministration of Complementary and Alternative Medicine
PHARMACOGENETICS AND PHARMACOGENOMICS OF CHEMOTHERAPEUTIC AGENTS IN CHILDREN
Thiopurines
Methotrexate
Glucocorticoids
Asparaginase
Vincristine
Anthracyclines
Cytarabine
Imatinib Mesylate
Etoposide
Cyclophosphamide
Platinum Compounds
Irinotecan
Temozolomide
Pharmacogenetics, Pharmacogenomics, and the Future
NEW DRUG DEVELOPMENT
Preclinical Development
Choice of Starting Dose for Clinical Studies
Dose Escalation Schemes
Parameter Estimates
STRATEGIES TO IMPROVE THE THERAPEUTIC INDEX
Dosage Based on Body Surface Area
Pathophysiologic Status
Dose Adaptation Using Pharmacokinetic-Pharmacodynamic-Pharmacogenetic Principles
CONCLUSION AND PERSPECTIVES

In the past two decades we have seen substantial advances in the number of available chemotherapeutic agents to treat a variety of neoplastic diseases, as well as in the discovery and development of new anticancer drugs, while our understanding of the biology and genetics of cancer continues to grow.[1,2,3,4] The tools at our disposal now include classes of molecules with highly distinct structures and innovative mechanisms of action and an impressive array of new techniques and novel uses for existing agents. In this chapter we will review the principles of chemotherapy in children, discuss the factors that influence individual responses to chemotherapy, and describe how pharmacokinetic, pharmacodynamic, and/or pharmacogenetic principles are used when conducting clinical trials that provide therapy tailored to individual patients.

CHEMOTHERAPEUTIC AGENTS

Chemotherapeutic agents used to treat pediatric cancer are generally similar to those used with adults, including conventional cytotoxic drugs and molecularly targeted agents. The former class can be subdivided into two large groups based on the dependence of their mechanism of action on the cell cycle. Cell cycle–nonspecific agents, which include alkylating agents, platinum agents, and most antitumor antibiotics, kill both quiescent and cycling tumor cells. Cell cycle–specific agents include antimetabolites and agents that interact with tubulin and topoisomerases. Conventional cytotoxic agents can target both malignant and normal cells and often cause adverse effects. During the past decade, the development of molecularly targeted chemotherapy has been revolutionized by a greater understanding of the biologic and genetic features of malignant disease.[2-4] Table 46-1 provides an overview of the drugs used to treat childhood cancers and their key pharmacologic features.

CLINICAL APPLICATION OF CHEMOTHERAPY

Chemotherapy has four major roles in the management of cancer: (1) primary cytoreduction therapy, (2) adjuvant therapy, (3) neoadjuvant therapy, and (4) site-directed therapy. Primary cytoreduction therapy is used when no superior alternative treatment is available (such as surgery and radiation therapy). Hematologic malignancies and some solid tumors of childhood are significantly chemosensitive and can be cured by serial courses of chemotherapy (e.g., induction, consolidation, and continuation therapy for acute lymphoblastic leukemia [ALL]). The chemosensitive malignancies also include acute myeloid leukemia (AML), lymphomas (both non-Hodgkin and Hodgkin), germ cell tumors, Wilms tumor, and embryonal rhabdomyosarcoma. Chemotherapy can also be used as an adjuvant therapy, wherein systemic treatment is applied to enhance local tumor control and to eradicate occult disseminated disease after surgery and/or radiation therapy. Occult residual disease at original sites and micrometastases are frequently present even after

TABLE 46-1 Key Features of Drugs Used in Pediatric Oncology

Drug (Trade Name; Chemical Class)	Mechanism of Action	Antitumor Activity	Route of Administration	Primary Pathway of Elimination	Enzymes and Transporters	Principal Adverse Effects
Alkylating Agents						
Mechlorethamine (Mustargen; nitrogen mustard, mustine, HN2)	Alkylation; DNA cross-linking	Hodgkin lymphoma (MOPP)	IV injection	Hydrolysis; liver	*N*-demethylation (CYP)	A, M, N&V, Mu, HU, Derm, V, Phleb, G, SM
Melphalan (Alkeran; mechlorethamine analogue)	Alkylation; DNA cross-linking	HDCT	IV injection or infusion; oral	Hydrolysis; renal	GSTP1, LAT1, ABCB1	A, M, N&V, D, Mu, Derm, Vas, Phleb, SIADH, G, SM
Chlorambucil (Leukeran; mechlorethamine analogue)	Alkylation; DNA cross-linking	Hodgkin lymphoma (ChlVPP)	Oral	Hydrolysis	GSTP1, ABCC2	A, M, N&V, HU, P, S, G, SM
Cyclophosphamide (Cytoxan; mechlorethamine analogue)	Alkylation (prodrug); DNA cross-linking	Leukemias, lymphomas, neuroblastoma, sarcoma	IV infusion; oral	Hydrolysis; liver	CYP2B6, CYP2C9, CYP3A4, CYP3A5, GSTA1, GSTP1, ALDH1A1, ALDH3A1	A, M, N&V, Cy, SIADH, C, P, G, SM
Ifosfamide (Ifex; mechlorethamine analogue)	Alkylation (prodrug); DNA cross-linking	Sarcomas, germ cell	IV infusion	Hydrolysis; liver	CYP2A6, CYP2B6, CYP3A4, CYP2C19, OCT2	A, M, N&V, Met, Cy, SIADH, NT, C, P, R, G, SM
Bendamustine (Treanda)	Alkylation; DNA cross-linking; blocks purine synthesis	Hodgkin lymphoma, lymphoma, leukemia	IV infusion	Liver	CYP1A2	M, N&V, H, P, PE, NT
Thiotepa (Thioplex; aziridine)	Alkylation; DNA cross-linking	HDCT	IV injection or infusion; intrathecal, intravesical	Liver	NA	A, M, N&V, HU, Derm, Cy, G, SM
Busulfan (Myleran; alkyl alkane sulfonate)	Alkylation; DNA cross-linking	HDCT	IV infusion; oral	Conjugation with glutathione; liver	CYP3A4, GSTA1, GSTP1	A, M, N&V, Mu, Derm, HU, AI, NT, VOD, P, S, G, SM
Carmustine (BiCNU; BCNU, nitrosourea)	Alkylation; DNA cross-linking; carbamoylation	Brain tumors, Hodgkin lymphoma, lymphoma	IV infusion; wafer implant (glioblastoma)	Chemical hydrolysis; liver	CYP	M, N&V, Phleb, S (wafer), C, H, P, R, G, SM

TABLE 46-1 Key Features of Drugs Used in Pediatric Oncology (Continued)

Drug (Trade Name; Chemical Class)	Mechanism of Action	Antitumor Activity	Route of Administration	Primary Pathway of Elimination	Enzymes and Transporters	Principal Adverse Effects
Lomustine (CeeNU; CCNU, nitrosourea)	Alkylation; DNA cross-linking; carbamoylation	Brain tumors, Hodgkin lymphoma, lymphoma	Oral	Chemical hydrolysis; liver	CYP2D6	M, N&V, NT, C, H, P, R, G, SM
Dacarbazine (DTIC, DTIC-Dome; imidazole-carboxamide)	Methylation inhibition (prodrug)	Hodgkin lymphoma, neuroblastoma, sarcomas	IV infusion	Chemical hydrolysis; liver, renal	N-demethylation (CYP); CYP1A2, CYP2E1	M, N&V, Flu, H
Procarbazine (Mutulane; imidazole-carboxamide)	Methylation inhibition (prodrug)	Brain tumors; Hodgkin lymphoma (ChlVPP)	Oral	Chemical hydrolysis; liver, renal	CYP, MAO	M, N&V, Mu, Flu, NT, Derm, G, SM
Temozolomide (Temodar; imidazole-carboxamide)	Methylation inhibition (prodrug)	Brain tumors	Oral	Chemical hydrolysis	CYP (minor)	M, N&V, NT, PE, H
Antimetabolites						
Cytarabine (Cytosar; Ara-C, cytosine arabinoside; cytidine analogue)	Incorporated into DNA; inhibits DNA polymerase; terminates DNA chain elongation	Leukemias	IV injection or infusion; intrathecal; SC	Activated to triphosphate; deamination	Cytidine deaminase, CNT1, ENT1, ENT2, ABCC4, ABCC11	M, N&V, Mu, GI, HU, Derm, HFS, PE, Conj, NT, H, PE
Azacytidine (Vidaza; cytidine analogue)	Hypomethylation of DNA (low dose)	MDS, AML	SC	Activated to triphosphate; chemical degradation; deamination	Cytidine deaminase	M, N&V, F, Mu, D, Inj, Derm
Decitabine (Dacogen; cytidine analogue)	Hypomethylation of DNA (low dose)	MDS, AML	IV infusion	Activated to triphosphate; chemical degradation; deamination	Cytidine deaminase	M, N&V, F, Mu, D, Derm
Gemcitabine (Gemzar; cytidine analogue)	Incorporated into DNA; inhibits DNA polymerase; terminates DNA chain elongation; inhibits ribonucleotide reductase (prodrug)	Solid tumors, lymphoma	IV infusion	Activated to triphosphate; deamination	Cytidine deaminase, CNT1, ENT1	M, N&V, Mu, D, F, Flu, Derm, NT, PE, H, R
Cladribine (Leustatin; adenosine analogue)	Incorporated into DNA; inhibits DNA polymerase; terminates DNA chain elongation; inhibits ribonucleotide reductase (prodrug)	Leukemias	IV infusion	Activated to triphosphate; renal; liver	Oxidative cleavage, oxidation, conjugation, CNT1, CNT2, CNT3, ENT1, ABCG2	M, N&V, D, Derm, NT

Continued on following page

TABLE 46-1 Key Features of Drugs Used in Pediatric Oncology (Continued)

Drug (Trade Name; Chemical Class)	Mechanism of Action	Antitumor Activity	Route of Administration	Primary Pathway of Elimination	Enzymes and Transporters	Principal Adverse Effects
Clofarabine (Clolar; adenosine analogue)	Incorporated into DNA; inhibits DNA polymerase; terminates DNA chain elongation; inhibits ribonucleotide reductase (prodrug)	Leukemias	IV infusion	Activated to triphosphate; extrahepatic	NA	M, N&V, D, C, H, R
Fludarabine (Fludara; adenosine analogue)	Incorporated into DNA; inhibits DNA polymerase; terminates DNA chain elongation; inhibits ribonucleotide reductase (prodrug)	AML, CML, indolent lymphomas	IV infusion	Activated to triphosphate; renal	NA	M, HA, Derm, fever, H, NT, TLS
Nelarabine (Arranon)	Incorporated into DNA; inhibits DNA synthesis	ALL	IV infusion	Activated to ara-guanine triphosphate; liver, renal	Adenosine deaminase	M, N&V, NT, P, PE
6-Mercaptopurine (Purinethol; hypoxanthine analogue)	Incorporated into DNA, RNA; blocks purine synthesis (prodrug)	ALL	Oral	Liver, renal (high dose)	TPMT, HGPRT, ENT2, OAT2, OAT3, ABCC4	M, H, Mu, N&V, HU, crystalluria, GI
6-Thioguanine (guanine analogue)	Incorporated into DNA, RNA; blocks purine synthesis (prodrug)	ALL, AML	Oral	Liver	TPMT, HGPRT, CNT3, ENT2, OAT3, ABCC5	M, H, Mu, N&V, HU, crystalluria
Hydroxyurea (Hydrea, Droxia)	Interferes with synthesis of DNA synthesis; inhibits ribonucleoside diphosphate reductase	ALL, AML	Oral	Liver, renal	OATP1B3, UT-A, UT-B1	M, H, Mu, N&V
5-Fluorouracil (fluoropyrimidine)	Incorporated into RNA, DNA; inhibits thymidine synthase (prodrug of 5′-DFUR)	Carcinomas, hepatic tumors	IV injection or infusion	Liver	DPD, GSTP1, hNT1, OAT2,	M, Mu, N&V, HFS, D, Derm, NT, C
Capecitabine (Xeloda; fluoropyrimidine)	Incorporated into RNA, DNA; inhibits thymidine synthase (prodrug of 5′-DFUR)	Colorectal cancer (in development)	Oral	Urine	CES2, CES1A1, cytidine deaminase, thymidine phosphorylase, DPD, CNT1, ABCA1	M, Mu, N&V, HFS, D, Derm, NT, C

TABLE 46-1 Key Features of Drugs Used in Pediatric Oncology (Continued)

Drug (Trade Name; Chemical Class)	**Mechanism of Action**	**Antitumor Activity**	**Route of Administration**	**Primary Pathway of Elimination**	**Enzymes and Transporters**	**Principal Adverse Effects**
Methotrexate (Trexall; antifolate)	Interferes with folate metabolism	Leukemias, lymphomas, osteosarcoma	Oral; IM; SC; IV injection; intrathecal	Renal	FPGS, GGH, OAT1, OAT2, OAT3, OAT4, OATP1A2, OATP1B1, OATP1B3, OATP4C1, RFC, PCFT, ABCB1, ABCC1, ABCC2, ABCC3, ABCC4, ABCG2	M, Mu, Derm, H, R, NT
Pemetrexed (Alimta; antifolate)	Interferes with folate metabolism	Various (in development)	IV infusion	Renal	NA	M, fatigue, Mu, HFS, Derm
Antitumor Antibiotics						
Bleomycin (Blenoxane)	Free radical–mediated DNA strand breaks	Lymphomas, germ cell tumor	IV injection; IM, SC	Renal	OCT6	P, Derm, fever, Mu, A, HSR, N&V
Dactinomycin (Cosmegen)	DNA cross-linking	Solid tumors	IV injection	Renal, liver	NA	M, Mu, N&V, D, A, H, V
Mitomycin C (Neulasta)	DNA cross-linking	Carcinomas	IV injection or infusion; intravesical	Liver	ABCB1	M, N&V, Mu, HU, anemia, VOD
Daunorubicin (Daunomycin; anthracycline)	DNA strand breaks (topo II)	ALL, AML, lymphomas	IV injection or infusion	Renal, liver	OCTN1, ABCB1, aldoketoreductase	M, Mu, N&V, D, A, C, V
Doxorubicin (Adriamycin; anthracycline)	DNA strand breaks (topo II)	ALL, AML, lymphomas, solid tumors	IV infusion	Liver	CYP2D6, CYP3A4, GSTP1, OCT6, OCTN1, ABCB1, ABCB5, ABCG2, aldoketoreductase	M, Mu, N&V, A, D, C, V
Epirubicin (Ellence; anthracycline)	DNA strand breaks (topo II)	Solid tumors, leukemia (in development)	IV infusion	Renal, liver	ABCB1, ABCC1, ABCG2, aldoketoreductase	M, Mu, N&V, A, C, V
Idarubicin (Idamycin; anthracycline)	DNA strand breaks (topo II)	ALL, AML, lymphomas	IV injection or infusion; oral	Renal, liver	ABCB1, aldoketoreductase	M, Mu, N&V, D, A, C, V
Mitoxantrone (Novantrone; anthracenedione)	DNA strand breaks (topo II)	ALL, AML, lymphomas	IV infusion; IP	Renal, liver	OCTN1, ABCB1, ABCG2	M, Mu, N&V, A, urine, veins and nail discoloration
Asparaginases						
l-Asparaginase (Elspar, Kidrolase; native asparaginase from *Escherichia coli*)	Depletion of plasma asparagine	ALL, lymphomas	IV infusion (>30 min), IM	Nonrenal	NA	HSR, thrombosis, GI, glucose intolerance, coagulopathy, hyperglycemia, H
Crisantaspase (Erwinase; Erwinia l-asparaginase, native asparaginase from *Erwinia chrysanthemi*)	Depletion of plasma asparagine	ALL, lymphomas	IV infusion (>30 min), IM	Nonrenal	NA	HSR, thrombosis, GI, glucose intolerance, coagulopathy, hyperglycemia, H

Continued on following page

TABLE 46-1 Key Features of Drugs Used in Pediatric Oncology (Continued)

Drug (Trade Name; Chemical Class)	Mechanism of Action	Antitumor Activity	Route of Administration	Primary Pathway of Elimination	Enzymes and Transporters	Principal Adverse Effects
Pegasparaginase (Oncaspar; PEG-asparaginase, from *E. coli*)	Depletion of plasma asparagine	ALL, lymphomas	IV infusion (1-2 hours)	Nonrenal	NA	HSR, thrombosis, GI, glucose intolerance, coagulopathy, hyperglycemia, H
Corticosteroids						
Dexamethasone (Decadron)	Receptor-mediated lympholysis	Leukemias, lymphomas	Oral, IV injection; IM	Liver	CYP3A4, ABCB1	Muscle weakness, osteoporosis, Derm, hypertension, N&V, headache
Prednisolone (Orapred OTD, Pediapred)	Receptor-mediated lympholysis	Leukemias, lymphomas	Oral; IV injection	Renal, liver	CYP3A4, sulfation, glucuronidation	Muscle weakness, osteoporosis, Derm, hypertension, N&V, headache
Prednisone (Deltasone)	Receptor-mediated lympholysis (prodrug)	Leukemias, lymphomas	Oral	Renal, liver	CYP3A4, sulfation, glucuronidation	Muscle weakness, osteoporosis, Derm, hypertension, N&V, headache
Platinum Compounds						
Carboplatin (Paraplatin)	Platination; DNA cross-linking	Brain tumors, neuroblastoma, sarcomas	IV infusion	Renal	CTR1, ATP7A	M, N&V, NT, EA, HSR
Cisplatin (Platinol)	Platination; DNA cross-linking	Testicular, brain tumors, osteosarcoma, neuroblastoma	IV infusion	Renal	GSTP1, OCT1, OCT2, CTR1, ABCC2, ABCC4, ATP7B, MATE1	N&V, R, NT, M, EA, O, HSR
Oxaliplatin (Eloxatin)	Platination; DNA cross-linking	Colorectal cancer, lymphoma (in development)	IV infusion	Renal	GSTP1, OCT1, OCT2, OCT3, OCTN1, OCTN2, MATE1, MATE2-K	NT, N&V, D, M, R, HSR
Retinoids						
All-*trans*-retinoic acid (ATRA; Vesanoid; tretinoin; retinol derivative)	Differentiation agent	Acute promyelocytic leukemia	Oral	Liver	CYP2C8, CYP2A6, CYP2B6, CYP2C9	Retinoic acid syndrome, pseudotumor cerebri, cheilitis
13-*cis*-retinoic acid (Accutane; retinol derivative)	Differentiation agent	Neuroblastoma	Oral	Liver	CYP2B6, CYP2C8, CYP2C9, CYP3A4/5, CYP2A6, CYP2D6	Cheilitis, conjunctivitis, dry mouth, xerosis, pruritus, headache

TABLE 46-1 Key Features of Drugs Used in Pediatric Oncology (Continued)

Drug (Trade Name; Chemical Class)	Mechanism of Action	Antitumor Activity	Route of Administration	Primary Pathway of Elimination	Enzymes and Transporters	Principal Adverse Effects
Topoisomerase-Interactive Agents						
Etoposide (VePesid; VP-16)	DNA strand breaks (topo II)	ALL, AML, lymphomas, neuroblastoma, sarcomas, brain tumors	IV infusion	Renal, liver	CYP3A4, CYP3A5, CYP1A2, CYP2E1, UGT1A1, OCTN2, OATP1B1, ABCB1, ABCC1, ABCC2	M, N&V, hypotension, HSR, SM
Teniposide (Vumon; VM-26)	DNA strand breaks (topo II)	ALL	IV infusion; oral	Liver	CYP3A4, ABCB1	M, N&V, HSR, hypotension, SM
Irinotecan (Camptosar; CPT-11; camptothecin analogue)	DNA strand breaks (topo I; prodrug of SN-38)	Rhabdomyosarcoma, solid tumors	IV infusion	Renal, liver	CYP3A4, CYP3A5, CYP2B6, CES2, UGT1A1, OATP1B1, ABCB1, ABCC2, ABCC4, ABCG2,	M, D, N&V, A, H
Topotecan (Hycamptin; camptothecin analogue)	DNA strand breaks (topo I)	Neuroblastoma; rhabdomyosarcoma	IV infusion	Renal	OAT3, ABCB1, ABCC4, ABCG2	M, Mu, D, N&V, A, Derm, H
Tubulin-Interactive Agents						
Docetaxel (Taxotere; taxanes)	Microtubule depolarization inhibitor	Solid tumors	IV infusion	Liver	CYP3A4/5, CYP2C8, OAT2, OATP1B3, ABCB1, ABCC2, ABCC10	M, HSR, A, NT, Derm, Mu
Paclitaxel (Taxol; Abraxane; taxane)	Microtubule depolarization inhibitor	Solid tumors	IV infusion	Liver	CYP2C8, CYP2C9, CYP3A4/5, OAT2, OATP1B1, OATP1B3, ABCB1, ABCC2, ABCC10	M, HSR, A, NT, M, C
Vinblastine (Velban; *Vinca* alkaloid)	Microtubule polarization inhibitor	Histiocytosis, Hodgkin lymphoma, testicular cancer	IV push or infusion	Liver	CYP3A4, CYP2D6, ABCB1, ABCC1, ABCC2, ABCC10, ABCG2	M, A, Mu, NT, V
Vincristine (Oncovin; *Vinca* alkaloid)	Microtubule polarization inhibitor	ALL, lymphomas, solid tumors	IV injection	Liver	CYP3A5, CYP3A4, ABCB1, ABCC1, ABCC2, ABCC10	NT, A, SIADH hypotension, V
Vinorelbine (Navelbine; *Vinca* alkaloid)	Microtubule polarization inhibitor	Solid tumor, Hodgkin lymphoma (in development)	IV injection of infusion	Liver	CYP3A4, CYP2D6	M, NT, A, V
Tyrosine Kinase Inhibitors						
Imatinib (Gleevec; STI-571, benzamide analogue)	Abl inhibitor	Ph+ CML, ALL	Oral	Liver	CYP3A4, CYP3A5, CYP2D6, CYP2C9, CYP2C19, OATP1A2, OATP1B3, OCT1, ABCB1, ABCC1, ABCC4, ABCG2	N&V, F, D, H, M

TABLE 46-1 Key Features of Drugs Used in Pediatric Oncology (Continued)

Drug (Trade Name; Chemical Class)	Mechanism of Action	Antitumor Activity	Route of Administration	Primary Pathway of Elimination	Enzymes and Transporters	Principal Adverse Effects
Dasatinib (Sprycel; carboxamide analogue)	Src-Abl inhibitor	Ph+ CML, ALL	Oral	Liver	CYP3A4, FMO3, OATP1B3, ABCB1, ABCC4, ABCG2	M, D, N&V, Derm, fatigue, P, headache
Nilotinib (Tasigna)	Abl inhibitor	Ph+ CML, ALL	Oral	Liver	CYP3A4, OATP1B1, OATP1B3, ABCB1, ABCG2	M, N&V, D, C, Derm, MS, P
Ponatinib (Iclusig)	Src-Abl inhibitor	Ph+ CML, ALL (in development)	Oral	Liver	CYP3A4, CYP2C8, CYP2D6, CYP3A5	M, N&V, D, C, Derm, H, GI, MS
Sunitinib (Sutent; carboxamide analogue)	VEGFR, PDGFR inhibitor	In development	Oral	Liver	CYP3A4, CYP1A2, OATP1B1, ABCB1, ABCG2	M, D, Derm, anorexia, hypertension, fatigue, headache
Sorafenib (Nexavar; carboxamide analogue)	Raf and FLT3 inhibitor	In development	Oral	Liver	CYP3A4, UGT1A9, OATP1B1, OATP1B3, ABCB1, ABCG2	M, D, Derm, anorexia, hypertension, fatigue, headache
Erlotinib (Tarceva; OSI-774, quinazolinamine analogue)	EGFR inhibitor	Solid tumors (in development)	Oral	Liver	CYP3A4/5, CYP1A2, ABCG2	Derm, D, anorexia, fatigue, N&V, dyspnea, fatigue
Gefitinib (Iressa; ZD1839, anilinoquinazoline analogue)	EGFR inhibitor	Solid tumors (in development)	Oral	Liver	CYP3A4/5, CYP2D6, OATP1B3, ABCB1, ABCG2	D, Derm, N&V
Crizotinib (Xalkori)	ALK inhibitor	ALCL, non–small cell lung cancer, neuroblastoma (in development)	Oral	Liver, Renal	CYP3A4/5, OATP1B1, OATP1B3, ABCB1	Ocular, N&V, Edema, H, NT
Pazopanib (Votrient)	Vascular endothelial growth factor inhibitor	Solid tumors (in development)	Oral	Liver	CYP3A4, CYP1A2, CYP2C8, OATP1B1, OATP1B3, ABCB1, ABCG2	D, N&V, M, H, C, MS, P
Vemurafenib (Zelboraf)	BRAF inhibitor	Melanoma	Oral	Liver	CYP3A4, OATP1B3, ABCB1	Derm, N&V, MS, PE
Proteasome Inhibitors						
Bortezomib (Velcade)	Proteasome inhibitor	Leukemia, lymphoma (in development)	IV injection, SC	Liver	CYP2C19, CYP3A4, CYP1A2	M, N&V, NT, D, P
Histone Deacetylase Inhibitors						
Vorinostat (Zolinza)	Histone deacetylase inhibitor	Leukemia, lymphoma (in development)	Oral	Liver, Renal	NA	D, N&V, PE, A, M, NT, R

TABLE 46-1 Key Features of Drugs Used in Pediatric Oncology (Continued)

Drug (Trade Name; Chemical Class)	Mechanism of Action	Antitumor Activity	Route of Administration	Primary Pathway of Elimination	Enzymes and Transporters	Principal Adverse Effects
Other Molecular Targeting Agents						
Arsenic trioxide (Trisenox)	Degrades PML-RARA and induces apoptosis	Acute promyelocytic leukemia, MDS	IV infusion	Hydrolysis	NA	C, NT, Derm, N&V, D, M, H, P
Everolimus (Afinitor)	mTOR kinase inhibitor	Solid tumor, leukemia, subependymal giant cell astrocytoma (in development)	Oral	Liver	CYP3A4, ABCB1	N&V, D, HR, P, PE, Derm, M, Mu
Temsirolimus (Torisel)	mTOR kinase inhibitor	Solid tumor, leukemia (in development)	IV infusion	Liver	CYP3A4, ABCB1	N&V, D, HR, P, PE, Derm, M, Mu
Ruxolitinib (Jakavi)	Janus kinase inhibitor	In development	Oral	Liver	CYP3A4	M, D, N&V, H, P, PE
Vismodegib (Erivedge)	Hedgehog inhibitor	In development	Oral	Liver	CYP2C9, CYP3A4, ABCB1	M, A, MS
Antibodies						
Rituximab (Rituxan)	CD20 antibody	Leukemia, lymphoma	IV infusion	NA	NA	M, N&V, F, PE, NT
Gemtuzumab ozogamicin	CD33 antibody, DNA double-strand break	AML	IV infusion	NA	NA	M, H, C, F, N&V, R
Brentuximab vedotin (Adcetris)	CD30 antibody, disrupt microtubule network	Hodgkin lymphoma, ALCL	IV infusion	Liver	CYP3A4	NT, F, PE, Derm, N&V, D, M, P
Alemtuzumab (Campath)	CD52 antibody	Leukemia, lymphoma, HSCT	IV infusion, SC	NA	NA	F, M, MS, C
Bevacizumab (Avastin)	Vascular endothelial growth factor antibody	Solid tumors (in development)	IV infusion	NA	NA	M, C, D, D, N&V, MS, P, R
Biological Response Modulator						
Aldesleukin (Proleukin)	Interleukin-2	Melanoma, leukemia, cell therapy	IV infusion, SC	Renal	NA	D, F, Flu, C, PE, Derm, N&V, M, R, P

macroscopic resolution of local disease. Before the routine use of adjuvant chemotherapy, 60% to 95% of children with localized solid tumors experienced relapse at primary or metastatic sites after receiving local control therapy alone. Thus the goal of adjuvant chemotherapy is to reduce the risk of local and systemic recurrence by eradicating microscopic residual disease or micrometastases in lungs, bone, bone marrow, lymph nodes, or other sites. The efficacy of adjuvant chemotherapy for Wilms tumor, Ewing sarcoma, rhabdomyosarcoma, osteosarcoma, and brain tumors (e.g., medulloblastoma) is well established. Neoadjuvant therapy may be used to reduce the size of primary and metastatic tumors, allow definitive surgical resection, and eradicate possible micrometastases when localized cancers cannot otherwise be optimally managed. This approach is often used with childhood solid tumors, including osteosarcomas, neuroblastomas, hepatoblastomas, and Wilms tumors. Examples of site-directed therapy include instillation of chemotherapy agents into sanctuary sites, such as intrathecal chemotherapy for leukemia and site-directed perfusion therapy (e.g., injection of agents into the feeding artery of tumors such as sarcomas in the extremities, liver tumors, and retinoblastoma).

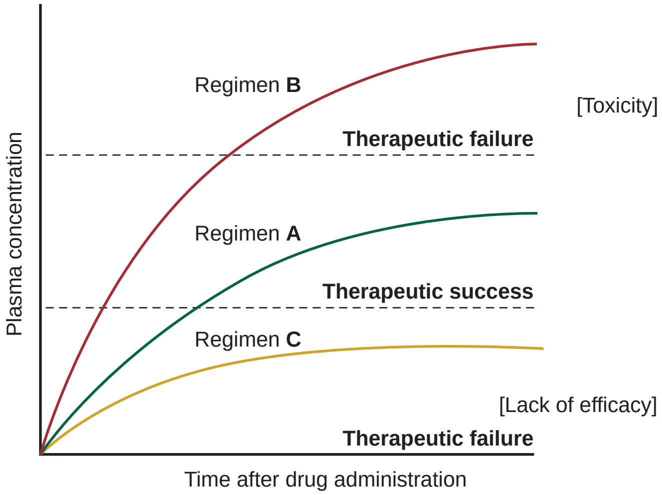

Figure 46-1 Narrow therapeutic index for chemotherapy administration. When a drug is given at a fixed dose and at fixed time intervals, it accumulates within the body until a plateau is reached. With regimen A, therapeutic success is achieved after a period of time. With regimen B, the therapeutic plasma concentration is achieved more quickly, but the plasma concentration ultimately becomes too high and causes toxicity. Regimen C does not reach therapeutic plasma concentration.

CHEMOTHERAPY IN CHILDREN

The current strategy is to administer chemotherapeutic agents at the maximum tolerated dose—that is, the dose just below that which causes unacceptable toxicity. This approach is based on a series of prospective and retrospective analyses showing that the greater the dose intensity (i.e., the dose delivered over a standard time interval), the better the outcome.[5,6] However, the narrow therapeutic index (i.e., the ratio of the theoretical minimum effective dose to the maximum tolerated dose) of most anticancer drugs demands a rigorous effort to optimize these regimens (Fig. 46-1). Effective systemic treatment requires judicious application of cytotoxic drugs that differ only slightly in their toxicity to normal cells and their therapeutic lethality to malignant cells. Pediatric oncologists and pharmacologists have studied multiple approaches in search of the best way to exploit this narrow therapeutic margin, including the use of drug combinations with different dose-limiting toxicities, the rescue or reconstitution of normal tissues (e.g., administration of leucovorin after methotrexate and use of bone marrow transplantation after high-dose chemotherapy), and the use of biologic modifiers to counteract specific mechanisms of resistance.

The therapeutic approaches used in adults cannot be directly transferred to growing children because certain agents have an extremely narrow therapeutic range in pediatric patients, and in most cases little or no information is available about the intrinsic sensitivity of a tumor to a particular agent and the tolerability of a given dose. Physiologic differences between children and adults, such as body composition, hepatic metabolism, and renal function, may affect the pharmacokinetics of a drug (i.e., drug disposition involving its absorption, distribution, metabolism, and excretion and the plasma concentration–time profile of the drug in the body) and thus the pharmacodynamics of a drug (i.e., drug action; the quantitative study of the effects of a drug, including efficacy and toxicity).[7,8] Children may also be more susceptible than adults to the toxicity of agents even when the pharmacokinetics are similar, as in the case of all-*trans*-retinoic acid for pseudotumor cerebri.[9] Further, pharmacokinetic studies have shown substantial interpatient variability in drug disposition and systemic drug exposure in children; these findings may underlie the observed variability in toxicity and response. The pharmacokinetics and pharmacodynamics of a drug, and thus its anticancer effects, are also influenced by physiologic factors that differ in children and adults, by drug-drug interactions, and by genetic influences (pharmacogenomics). Although pediatric cancer is rare compared with adult cancer, optimizing treatment in a patient group with a higher cure rate and a longer expected survival becomes critical to minimize the incidence of preventable acute and late complications in children while maintaining efficacy.

PHARMACOKINETIC CHANGES DURING CHILDHOOD

Pharmacokinetic parameters include half-life ($T_{1/2}$), area under the plasma concentration versus time curve (AUC), bioavailability, volume of distribution (Vd), steady state concentration, and clearance (Table 46-2). Body composition and organ function at the extremes of age can affect drug disposition and effect.[10,11] Changes as a child develops and matures may alter absorption, distribution, metabolism, and excretion of chemotherapeutic agents (Fig. 46-2).

The importance of understanding the influence of age on the pharmacokinetics and pharmacodynamics of

TABLE 46-2 Pharmacokinetic Parameters

Parameter	Units	Definition
Half-life ($T_{1/2}$)	Time (h)	The time necessary to halve the plasma concentration. Useful for determination of frequency of drug administration to obtain the desired plasma concentration. The half-life of a particular drug is usually independent of the dose administered. However, it may change according to the saturation of a mechanism (e.g., elimination, catabolism, or binding to plasma proteins).
Area under the curve (AUC)	Concentration × time (μM × h)	Calculated as *f* ([C] × Dt); [C] is measured concentration and Dt is the interval of time between two measurements. The integral of the plasma concentration versus an interval of definite time. It represents an important quantitative measure of total systemic drug exposure. Also, it is required for the calculation of other pharmacokinetic parameters such as clearance and bioavailability.
Bioavailability (F)	Fraction (%)	The percentage of the administered drug concentration that is achieved in the central compartment. Generally measured by comparing the AUCs obtained after intravenous administration with those obtained after oral administration. For example, the AUC obtained after intravenous administration usually corresponds to bioavailability (i.e., 100%). After oral administration, the AUC corresponds at best to an identical bioavailability; it is generally lower.
Volume of distribution (Vd)	Volume (L)	The fictitious volume in which the drug would have been distributed by supposing that its concentration is homogeneous (i.e., the average tissue concentration is identical to that of plasma). Expressed as Vd = dose/C0 (initial concentration). For example, after intravenous injection of 100 mg of a drug whose initial concentration, C0, in plasma is 10 mg/L, the volume of distribution is 10 L. For a given drug, the knowledge of its desired concentration in blood and of its volume of distribution allows evaluation of the dose to administer.
Steady state concentration (Css)	Concentration (μM)	The state of equilibrium obtained at the end of a certain number of administrations. To obtain an increase in the plasma concentration with repeated administrations, it is necessary that a residual concentration persists at the time of the following administration. At the steady state, if the dose and the frequency of administration remain constant, the concentration obtained will also be constant. The steady state is usually obtained at the end of approximately five half-lives.
Clearance (Cl)	Volume/Time (mL/min)	Defined as the theoretic volume from which drug is completely removed per unit time. Plasma clearance is the apparent volume of plasma from which drug is cleared per unit of time. Total clearance is the fraction of the volume of distribution, Vd, which is completely cleared per unit of time. The total clearance depends on the constant of elimination and thus on $T_{1/2}$ and on Vd, which is considered to be sum of metabolic and spontaneous chemical degradation, as well as biliary/fecal and renal elimination.

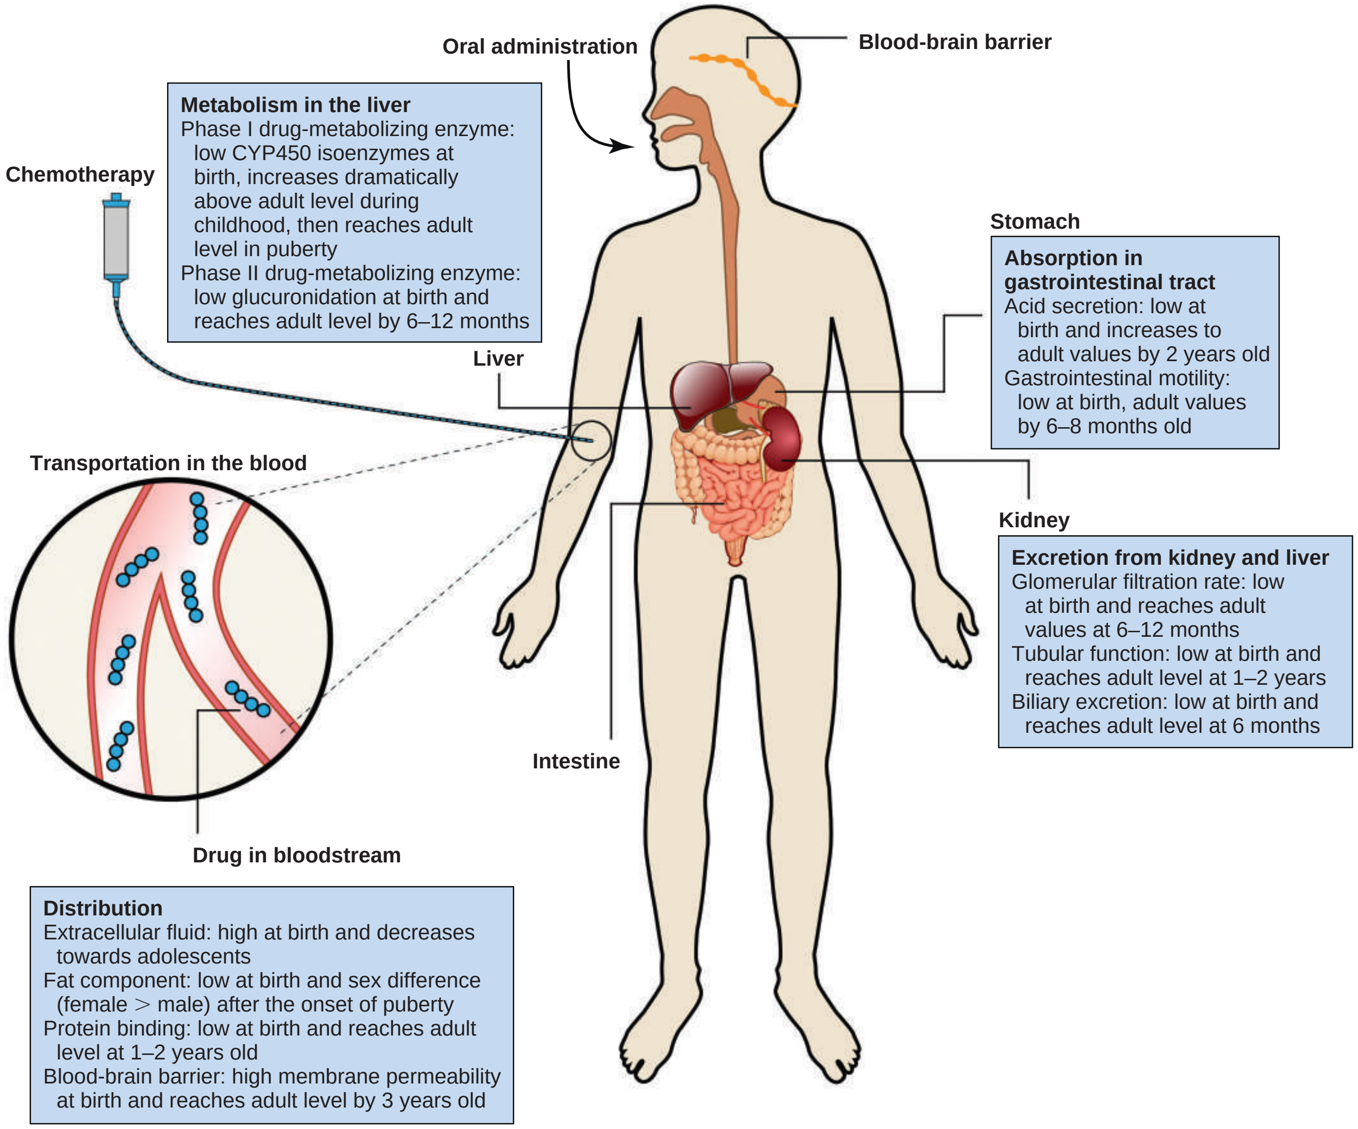
individual anticancer agents has increased steadily with advances in the treatment of infant and childhood malignancies. Although the influence of age has been formally evaluated for a limited number of cytotoxic drugs, further efforts to improve the individualization of drug therapy on the basis of maturation and development are necessary to enhance the odds of therapeutic success.

Absorption

Medications are typically administered via the gastrointestinal tract (mainly orally), intravenously (IV), intramuscularly, and via the skin (subcutaneous or transdermal). Orally administered agents must surmount multiple barriers to reach the systemic circulation (Figs. 46-2 and 46-3). Gastric pH, gastrointestinal motility, transporter-mediated uptake and efflux, and metabolism before a drug enters the systemic circulation play important roles in the absorption of many drugs. Although chemotherapy is rarely administered intramuscularly or transdermally, the lack of muscle and fatty tissue in newborns and infants and their thin skin would cause erratic absorption and increase the risk of toxicity.

Gastric pH is neutral during the first few weeks of life and does not approximate adult values until the age of 2 years, which may affect the bioavailability of compounds.[7,8] Higher pH delays the absorption of weak acids and increases the absorption of weak bases. Methotrexate absorption, for example, is significantly reduced by coadministration with milk, which may further increase gastric pH.[12] The solubility of tyrosine kinase inhibitors (e.g., dasatinib and nilotinib) is also dependent on pH.[13] Further, pH-dependent drug degradation in the stomach affects the quantity of intact drug that reaches the small intestine. Absorption of lipophilic drugs requires their micellar solubility, which is dependent on biliary acids, whose secretion in turn is affected by food intake. Bile acid secretion is low at birth and increases to the adult level at approximately 6 months.

Gastric emptying time varies with gestational age and is typically longer in premature infants and neonates than in older children.[14] Low gastrointestinal motility persists until 6 to 8 months of age and may cause delayed absorption or increased absorption because of greater contact time. In addition, drugs may be administered in altered



Metabolism in the liver
Phase I drug-metabolizing enzyme: low CYP450 isoenzymes at birth, increases dramatically above adult level during childhood, then reaches adult level in puberty
Phase II drug-metabolizing enzyme: low glucuronidation at birth and reaches adult level by 6–12 months

Absorption in gastrointestinal tract
Acid secretion: low at birth and increases to adult values by 2 years old
Gastrointestinal motility: low at birth, adult values by 6–8 months old

Excretion from kidney and liver
Glomerular filtration rate: low at birth and reaches adult values at 6–12 months
Tubular function: low at birth and reaches adult level at 1–2 years
Biliary excretion: low at birth and reaches adult level at 6 months

Distribution
Extracellular fluid: high at birth and decreases towards adolescents
Fat component: low at birth and sex difference (female > male) after the onset of puberty
Protein binding: low at birth and reaches adult level at 1–2 years old
Blood-brain barrier: high membrane permeability at birth and reaches adult level by 3 years old

Figure 46-2 Pharmacokinetic changes during childhood development. Changes in body composition and organ function during childhood development can affect drug disposition and effects by altering absorption, distribution, metabolism, and excretion of chemotherapeutic agents. *CYP450,* Cytochrome P450.

forms to small children. For example, tablets may be crushed and added to food or slurries/suspensions and sometimes may be given via nasogastric tube, which may alter their rate and extent of absorption.

Transporter proteins are involved in drug uptake and movement across the intestinal epithelium (Fig. 46-3). Intestinal epithelial cells contain several uptake transporters, including one or more members of the organic anion-transporting polypeptide (OATP) family, peptide transporter (PEPT)–1 (PEPT1; solute carrier [SLC]–15A1 [SLC15A1]), ileal apical sodium/bile acid cotransporter (SLC10A2), and monocarboxylic acid transporter 1 (SLC16A1) in their apical (luminal) membranes (Fig. 46-4, *A*). Adenosine triphosphate–binding cassette (ABC) transporters such as ABCB1 (P-glycoprotein, multidrug resistance protein [MDR]-1), ABCC1 (multidrug resistance-associated protein [MRP]–1), ABCC2 (MRP2), and ABCG2 (breast cancer resistance protein [BCRP]) are located on the apical membranes of intestinal epithelial cells, where they secrete substrates back into the intestinal lumen, thereby limiting intestinal absorption and decreasing bioavailability.[15,16] The basolateral membranes of intestinal epithelial cells contain organic cation transporter–1 (OCT1; SLC22A1), heteromeric organic solute transporter α-β, and ABCC3 (MRP3). Some drugs are eliminated by hepatocytes into the bile before they are metabolized (Figs. 46-3 and 46-4, *B*). Phase I (e.g., cytochrome P [CYP]–450) and phase II (e.g., glutathione *S*-transferase) drug-metabolizing enzymes in the gastrointestinal tract can metabolize drugs before they enter the systemic circulation (see Fig. 46-3). Although the data are limited, some studies have shown that developmental changes in at least some of these enzyme activities and transporter proteins can affect drug absorption.[17-19]

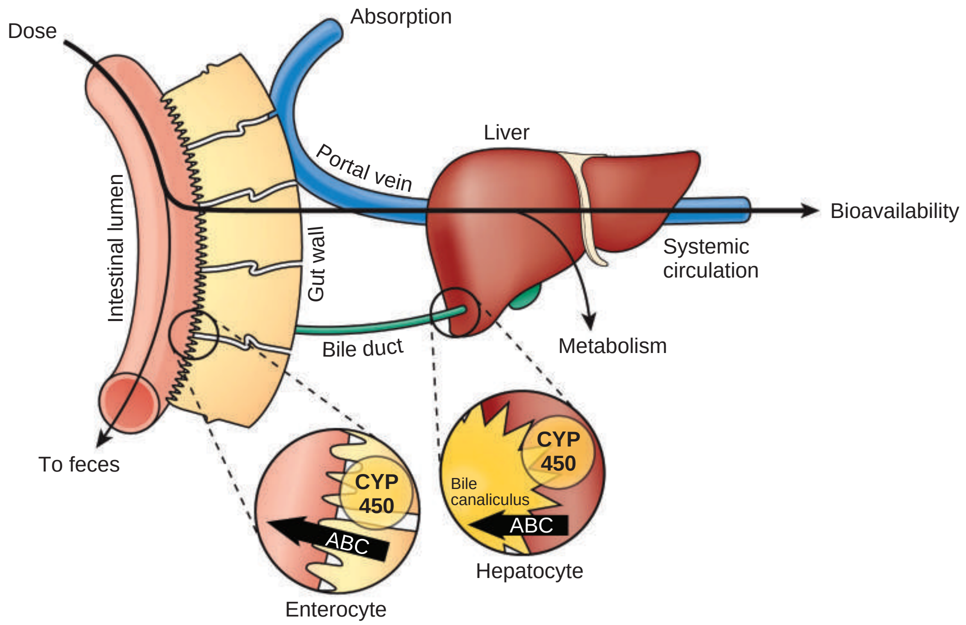


Figure 46-3 Absorption of orally administered medications and their bioavailability and metabolism. The role of active transport toward the gut lumen and bile by adenosine triphosphate–binding cassette *(ABC)* transporters expressed in the intestinal epithelium and liver, respectively, after oral administration of chemotherapeutic agents. Cytochrome P450 *(CYP450)* isoenzymes can metabolize drugs before they reach systemic circulation.

Volume of Distribution

The volume of distribution (Vd) of a systemically absorbed drug is the extent to which the drug penetrates extravascular tissues (see Fig. 46-2 and Table 46-2). Vd is affected by body composition (water and fat) and plasma proteins. Changes in body composition between birth and adolescence can alter pharmacokinetic parameters. The proportions of body water compartments, particularly extracellular fluid volume, change dramatically between birth and adulthood; extracellular fluid volume represents 50% of body weight in premature infants, 35% in infants 4 to 6 months old, and 20% in adolescents and adults.[20] Thus polar drugs, which are distributed primarily in body water, will have a larger volume of distribution in infants than in older children and adults. The net result of an isolated increase in Vd is a lower peak concentration and prolonged terminal half-life, assuming that drug clearance remains unchanged.

Newborns have less skeletal muscle mass and subcutaneous fat than do older infants. Fat components gradually increase after birth, but they differ in boys and girls after the onset of puberty. During adolescence, boys actually lose body fat (reaching a mean of 12% of body weight), whereas girls gain body fat (reaching a mean of 25% of body weight). Therefore gender-related differences in Vd and clearance of lipophilic drugs may be more prominent during adolescence than in preadolescent children or older adults.

Drug distribution may also be affected by plasma proteins. Theoretically, drug displacement from blood components by lower protein binding increases the apparent distribution volume. Although the resulting increase in the free drug fraction may make the drug more available to its target, it also enhances metabolic and renal elimination. Protein binding may be reduced because of persistence of fetal albumin or by low plasma protein content, particularly albumin, α1-acid glycoprotein, and gamma globulin.[21,22] Although the protein binding of acidic drugs may reach adult levels between 1 and 2 years of age, adult gamma-globulin levels are not reached until age 7 to 12 years.

One unique aspect of infancy is the immaturity of specific organs. For example, the myelin content of the brain is lower in newborns. Because of incomplete maturation of the blood-brain barrier (which reaches adult level by age 3 years), membrane permeability is greater in the infant brain, and the brain-to-plasma ratio of some drugs has been shown to vary with age.[23,24]

Hepatic Metabolism

The liver plays an important role in drug metabolism (see Fig. 46-2). Drug-metabolizing enzymes are divided into two classes: phase I (oxidation, reduction, hydrolysis, or demethylation) and phase II (conjugation or coupling of endogenous molecules, including glucuronide, sulfate, acetate, amino acid, methyl, and glutathione moieties, to the parent drug or a phase I metabolite; Table 46-3). Immature organ systems in infants and young children can alter the disposition of many classes of drugs, including antibiotics, anticonvulsants, and antineoplastic agents.[7,8,10] Phase I enzymes (e.g., CYP450 microsomal enzymes) are highly expressed in the liver. They can diminish the pharmacologic activity of a drug but can also convert a prodrug to its biologically active form (e.g., cyclophosphamide and codeine). CYP3A4 is the phase I

enzyme involved in the metabolism of the largest number of drugs, followed in approximate order by CYP2D6, CYP2C8/9/19, CYP1A2, CYP2B6, CYP2A6, and CYP2E1.[7] CYP3A7 is highly expressed in the fetus and then decreases rapidly after birth.[25] The metabolic activity of other CYP450 enzymes (e.g., CYP3A4, CYP2D6, and CYP2C9) is low in neonates but increases dramatically between age 2 weeks and 3 years. Clearance rates by CYP450 enzymes rise from 20% of that in adults to two to six times that in adults between infancy and adolescence, and then they decline gradually to adult values during puberty.[26] Low hydrolysis rates have been reported for drugs such as procaine in premature infants and neonates, but normal activity is measurable by 12 months. Phase II glucuronidation is almost exclusively a detoxification mechanism that inactivates a compound and facilitates its excretion by enhancing its hydrophilicity and its recognition by biliary canicular efflux proteins. The activity glucuronidation enzyme rises to 30% of adult activity by 3 months of age and then reaches adult levels between 6 and 12 months of age.[27] Esterase activity, which is important for the metabolisms of agents such as irinotecan, gradually increases during the first year of life.[28]

Renal and Hepatic Excretion

The kidney is predominantly responsible for excretion of drugs and their metabolites (see Fig. 46-2). The immature kidney has a low glomerular filtration rate (GFR). In full-term infants, the GFR is 40 mL/min/1.73 m^2 and varies

TABLE 46-3 Drug Metabolizing Enzymes

Enzymes	Reactions
Phase I Enzymes	
Cytochrome P450s	C and O oxidation, dealkylation, others

substantially among individuals.[29,30] The GFR gradually increases, reaching adult values between age 6 and 12 months. Tubular function and passive resorption may also be significantly lower in the neonate. Because tubular resorption matures more slowly than does glomerular filtration, toddlers may have remarkably high clearance rates for compounds that undergo tubular resorption in older children.

GFR, as assessed by technetium-99m diethylenetriamine pentaacetic acid filtration, was related to body surface area (BSA) in children 2 months to 17 years of age, but GFR was not related to age when normalized to BSA.[29] Premature and term infants require dose adjustments based on GFR measurement or estimation for drugs eliminated primarily by glomerular filtration, such as carboplatin. Formulas are available for estimation of creatinine clearance in infants and older children on the basis of serum creatinine and height[30,31] or on another endogenous surrogate marker of GFR, such as cystatin C.[32]

Many drugs are excreted in bile as the parent compound or as a metabolite. Biliary excretion favors compounds that have a molecular weight greater than 300 and contain both polar and lipophilic groups. Conjugation, particularly with glucuronate, increases biliary excretion. After the bile empties into the intestine, a fraction of the drug may be reabsorbed and eventually return to the liver (enterohepatic cycling). The remainder is excreted into the feces. Biliary excretion is low at birth and reaches adult levels at approximately 6 months of age.

Many SLC family transporters and ABC family transporters have been identified; these transporters mainly facilitate cellular drug uptake and elimination in kidney and liver (see Fig. 46-4, *B* and *C*).[33] The apical (luminal) membranes of renal proximal tubules contain organic anion transporter (OAT)–4 (OAT4, SLC22A11), urate transporter–1 (SCL22A12), PEPT1 (SLC15A1) and PEPT2 (SLC15A2), ABCC2 and ABCC4 (MRP4), multidrug and toxin extrusion (MATE) protein–1 (MATE1, SLC47A1), ABCB1, organic cation/ergothioneine transporter (OCTN1; SLC22A4), and organic cation/carnitine transporter (OCTN2; SLC22A5). The basolateral membranes of the proximal tubules contain the uptake transporters OATP4C1 (SLCO4C1); OCT2; and OAT1, OAT2 (SLC22A7), and OAT3 (SLC22A8).

Uptake transporters in the hepatocyte basolateral (sinusoidal) membrane include the sodium/taurocholate cotransporting peptide (SLC10A1), three members of the OATP family (OATP1B1 [SLCO1B1], OATP1B3 [SLCO1B3], and OATP2B1 [SLCO2B1]), OAT2 and OAT7 (SLC22A9), and OCT1. Efflux pumps in the hepatocyte basolateral membrane include ABCC1 (MRP1), ABCC3, ABCC4, ABCC5 (MRP5), and ABCC6 (MRP6). Apical (canalicular) efflux pumps of the hepatocyte comprise ABCB1, ABCC2, ABCB3 (transporter associated with antigen processing 2 [TAP2]), ABCB11 (bile salt export pump [BSEP] or sister of P-glycoprotein [SPGP]), ABCG2, and MATE1.

ABCB1 activity in lymphocytes peaks at birth, decreases between ages 0 and 6 months, and stabilizes at the adult level between the ages of 6 months and 2 years.[34] Developmental changes in the functions of other transporters have not been fully defined, but many are under investigation.

Influence of Underlying Disease on Metabolism

Pathophysiologic changes associated with specific pediatric malignancies may alter drug disposition. For example, the clearance of antipyrine and lorazepam was observed to increase between diagnosis and the end of remission induction therapy in children with ALL.[35] The clearance of unbound teniposide is lower in children with relapsed ALL than during first remission.[36] Because leukemic infiltration of the liver is common at the time of diagnosis of ALL, drugs metabolized by the liver may have reduced clearance, as has been documented in preclinical models.[37]

In mouse models, certain tumors elicited an acute-phase response that coincided with downregulation of human hepatic CYP3A4 and of the mouse orthologue Cyp3a11.[38] The reduction of murine hepatic *Cyp3a* gene expression in tumor-bearing mice resulted in decreased Cyp3a protein expression and consequently a significant reduction of Cyp3a-mediated metabolism of midazolam. These findings support the possibility that tumor-derived inflammation may alter the pharmacokinetic and pharmacodynamic properties of CYP3A4 substrates, leading to reduced drug metabolism in humans.

Unique Drug Effects in Pediatric Patients

Experience has shown that children often tolerate the conventional toxicities of chemotherapy better than adults, and that children (with the exception of neonates) experience very low regimen-related mortality. This finding may be partly explained by relatively low drug exposure caused by higher drug clearance rather than by altered pharmacodynamics. Lower exposure may explain briefer periods of neutropenia, less mucositis, and rare hepatic veno-occlusive disease. Children's greater ability to tolerate intensive therapy may partly explain why children with ALL have a higher cure rate compared with adults.[39,40]

However, the immature organ systems of the very young may be more susceptible to certain aspects of toxicity, including late cardiomyopathy, neuron developmental disorders, delayed puberty, growth plate arrest, and infertility. Children appear to be more sensitive to the cardiotoxic effects of anthracyclines (e.g., doxorubicin, daunorubicin, idarubicin, and mitoxantrone).[41,42] Follow-up studies have shown that months or years after intrathecal therapy for central nervous system (CNS) leukemia, with or without cranial irradiation, children treated for ALL may experience a chronic demyelinating encephalopathy and/or cognitive late effects.[43,44] Further, the latent effects of chemotherapy on fertility appear to vary with the developmental stage of the patient at the time of treatment. Treatment of leukemia and lymphoma in prepubertal boys, for example, does not appear to produce sustained testicular damage unless large cumulative doses of alkylating agents (e.g., cyclophosphamide >6 g/m^2) are used.[45] Treatment during puberty is more likely to permanently damage the germinal epithelium, although sexual maturation may proceed on a normal schedule.[46] Most prepubertal girls treated for leukemia with antimetabolites achieve menarche and progress through puberty.[47] Ovarian failure is associated mainly with alkylating agents and gonadal radiotherapy and is directly related to cumulative dose and age at exposure.[48] Nearly 30% of survivors treated with alkylating agents and abdominal-pelvic irradiation experienced nonsurgical primary ovarian failure (defined as cessation of menses before age 40 years).[49] Procarbazine exposure at any age, cyclophosphamide exposure from age 13 to 20 years, and ovarian radiation doses greater than 10 Gy were independent risk factors for acute ovarian failure (defined as loss of ovarian function within 5 years after diagnosis).[50] Most girls treated for brain tumors with procarbazine and/or nitrosourea and with neuraxis radiation showed evidence of ovarian hormonal failure.[51]

DRUG INTERACTIONS

Combination Chemotherapy

The vast majority of pharmacologic studies of anticancer agents have modeled the effects of a single drug. However, as a consequence of somatic mutations and/or selection of genetically resistant clones, tumor cytotoxicity tends to diminish over subsequent courses of single-agent treatment. Therefore cancer chemotherapy is most frequently given as a combination of drugs that individually have shown activity against the specific cancer to be treated but that have different pharmacologic mechanisms of action. The selection of agents that exert maximal anticancer effects and minimal adverse effects requires a clear understanding of the biochemical, molecular, and pharmacokinetic mechanisms of action and of individual and overlapping toxicities of the agents. The treatment for ALL provides an example of excellence.[3] Most of the drugs used were developed before 1970. However, their dosage and schedule of administration have been optimized on the basis of leukemic-cell biologic features, response to therapy (e.g., minimal residual disease), and patient pharmacodynamic and pharmacogenomic findings. The 5-year survival rate for pediatric ALL has been approximately 90% in recent trials.[52]

Optimal combination chemotherapy theoretically should meet the following criteria:

- Drugs that show single-agent activity should be selected. Because of primary resistance, rates of complete response to a single agent rarely exceed 20%.
- Drugs with different mechanisms of action should be combined. The various classes of anticancer agents have different cellular targets. The use of multiple agents with different mechanisms of action enables independent killing of cells by each agent. Cells resistant to one agent may be sensitive to another drug or drugs in the regimen. Known patterns of cross-resistance must be taken into consideration.
- Drugs with different mechanisms of resistance should be combined. Resistance to many agents may be the result of mutations selected by those agents. However, a single mutational change can also cause resistance to multiple drugs. The number of known mechanisms of resistance is continuously increasing and is partly drug dependent. Because drug-resistant mutants may be present at the time of clinical diagnosis, the earliest possible use of non–cross-resistant drugs is recommended to avoid the selection of double mutants. Adequate cytotoxic doses of drugs must be administered as frequently as possible to achieve maximal killing of sensitive and moderately resistant cells.
- If possible, drugs with different dose-limiting toxicities should be combined, because it is more likely that drugs with nonoverlapping toxicities can be used at the full dosage, optimizing their potential effectiveness.

As noted, multidrug therapy can give rise to clinically important drug-drug interactions, which typically occur when the pharmacokinetic behavior of one drug is altered by the other (Fig. 46-5 and Table 46-1). These interactions are important in the design of drug combinations, because diminished therapeutic efficacy or increased toxicity of one or more of the administered agents can occur. Combinations of drugs may also show pharmacodynamic interactions that cannot be explained by altered pharmacokinetic profiles. Some of these interactions are at the cellular level or are related to the cell cycle. Interactions can be classified as synergistic (i.e., the effect of the combination is greater than the sum of the individual effects), additive (the effect of two drugs is the sum of the effects of each), or antagonistic (the effect of two drugs is less than the sum of their individual effects). Provided that the drugs used are active against a particular disease,

Figure 46-5 The main cytochrome P450 isoenzyme–inducing and P450 isoenzyme–inhibiting agents used in pediatric oncology. Drugs listed in *red* are inhibitors and those listed in *green* are inducers of the cytochrome P450 enzyme system.

knowledge of cellular kinetics can be used to consider the use of non–cell cycle phase-specific agents (e.g., alkylating agents, platinum agents, and anthracyclines), first to reduce tumor bulk and second to recruit slowly dividing cells into active deoxyribonucleic acid (DNA) synthesis. After the latter is achieved, treatment can be continued with cell-cycle phase-specific agents (e.g., methotrexate or fluoropyrimidines), which affect cells mainly during DNA synthesis. Similarly, repeated courses of S-phase–specific drugs, such as cytarabine and methotrexate, are most effective if administered during the rapid rebound recovery of DNA synthesis that follows suppression of DNA synthesis in the previous course.[53] If pharmacokinetic and pharmacodynamic interactions exist, the drug doses and sequence of administration that allow safe administration of combination chemotherapy are typically defined during early clinical trials (i.e., phase I and phase II studies).

Coadministration of Non-Anticancer Drugs

Many prescription and over-the-counter medications are used during chemotherapy to improve quality of life or to treat other diseases, but they may interact with anticancer agents, thus altering their pharmacokinetic characteristics, clinical effectiveness, and/or toxicities.[54,55,56] More than 100,000 deaths per year in the United States alone are attributed to drug-drug interactions, placing these interactions between the fourth and sixth leading cause of death.[57] Clearly, all aspects of pharmacokinetics (i.e., absorption, distribution, metabolism, and excretion) may be affected when a drug is given in combination with another drug. The generally narrow therapeutic index of cytotoxic chemotherapy means that drug-drug interactions would predispose some persons to excessive toxicity or inadequate efficacy.

Pharmacokinetic Interactions Affecting Drug Absorption

Because many chemotherapeutic agents are given via an IV line, factors that affect absorption have little effect on their pharmacokinetics. However, absorption plays a crucial role in the bioavailability of orally administered drugs; absorption is contingent on adequate intestinal uptake and circumvention of intestinal and subsequent hepatic metabolism of the drug (see Figs. 46-2 and 46-3).[13,58,59] Food intake can delay gastric emptying, raise intestinal pH, increase hepatic blood flow, and slow gastrointestinal transit, which may significantly affect the pharmacokinetic profile of orally administered medications.[55] Mercaptopurine is metabolized by xanthine oxidase into inactive metabolites. Ingestion of foods that contain xanthine oxidase, such as dairy products, can reduce the effectiveness of mercaptopurine.[58] Therefore patients are instructed to take mercaptopurine on an empty stomach, preferably at night (2 hours after food intake).[56] Proton-pump inhibitors and antacids increase gastric pH and decrease the solubility and absorption of tyrosine kinase inhibitors (with the exception of imatinib).[60]

Another important mechanism of interaction with orally administered anticancer agents is their affinity for ABC transporters (e.g., ABCB1, ABCC1, ABCC2, and ABCG2), which are located on the apical membranes of intestinal epithelial cells and secrete substrates from the epithelial cell back into the intestinal lumen, thereby limiting intestinal absorption and bioavailability (see Figs. 46-3 and 46-4, *A*).[15,16] Some chemotherapeutic agents are substrates of these transporters, the activity of which may be inhibited by other medications, foods, and herbal products. In addition, extensive metabolism of anticancer drugs in the gut wall and/or the liver (e.g., by CYP450 enzymes) during the first pass can keep them out of the systemic circulation and is another potential drug-drug interaction mechanism (see Fig. 46-3). An ideal chemotherapeutic drug would have an adequate absolute bioavailability, as shown by little drug-drug interaction or interpatient/intrapatient variability in absorption. However, the most commonly used oral agents, including mercaptopurine, methotrexate, etoposide, and cyclophosphamide, do not meet these criteria.

Pharmacokinetic Interactions Affecting Drug Distribution

Chemotherapeutic agents can bind to several blood components, including albumin, lipoproteins, immunoglobulins, and α1-acid glycoprotein, and the increased free-drug fraction caused via displacement by another drug may make the displaced drug more available to the target and enhance metabolism and elimination.[55] Highly protein-bound drugs, such as warfarin, may interact with protein-bound cytotoxic drugs such as etoposide and paclitaxel. The hematologic toxicity of etoposide is more closely related to systemic exposure to the unbound drug than to the total drug.[61] However, the therapeutic implications of displacement of many anticancer drugs from their protein-bound state are as yet undefined.

Pharmacokinetic Interactions Affecting Drug Metabolism

Most important drug-drug interactions involve altered liver metabolism—for example, altered expression or functionality of CYP450 isoenzymes, such as CYP3A4, 2C9/8, 2D6, and 2C19 isoforms, which oxidize anticancer drugs to more polar and usually inactive metabolites (see Table 46-1).[62] Induction of CYP450 activity, which increases a drug's metabolic rate, may reduce plasma drug concentration and thus reduce the therapeutic effect. For example, anticonvulsant drugs (such as phenytoin, phenobarbital, and carbamazepine) induce drug-metabolizing CYP450 enzymes and thereby increase the clearance of various anticancer agents (e.g., anthracyclines, epipodophyllotoxins, and vinca alkaloids) in children (see Table 46-1 and Fig. 46-5).[56,63] Enzyme-inducing anticonvulsants have been shown to be associated with lower event-free survival, hematologic relapse, and CNS relapse in persons with ALL.[63] Conversely, suppression (inhibition) of CYP450 activity may increase plasma drug concentration, causing greater toxicity commensurate with overdose. Valproic acid, azole antifungals (e.g., fluconazole, voriconazole, and posaconazole), the antiemetic aprepitant, and macrolide antibiotics (e.g., clarithromycin, erythromycin, and azithromycin) should be avoided or prescribed with caution when CYP450-metabolized chemotherapeutic agents are given concomitantly.[56] Although drugs are typically metabolized to their inactive forms, prodrugs such as cyclophosphamide are metabolized to their active forms by CYP450 enzymes and have the opposite consequences of metabolic inhibition or activation.

Pharmacokinetic Interactions Affecting Drug Excretion

ABC transporters such as ABCB1, ABCC1/2, and ABCG2 are involved in drug elimination.[33] ABCB1 in the brush-border membrane of the proximal renal tubule plays an important role in renal elimination of chemotherapeutic agents by active secretion into the urine (see Fig. 46-4, *C*). Inhibition of ABCB1 can result in increased systemic exposure and tissue distribution of drugs that are ABCB1 substrates (see Table 46-1), whereas induction of ABCB1 leads to decreased systemic exposure. ABCB1 is also expressed in canalicular membranes of the liver; it has a role in elimination of drugs into bile, from which they can be reabsorbed in the intestine or eliminated in the feces (see Fig. 46-4, *B*). Excretion of irinotecan and its metabolites is mediated by several ABC transporters (e.g., ABCB1 and ABCG2).[64] Substrates and/or inhibitors of these transporters (e.g., cyclosporine and gefitinib) may interfere with renal and/or biliary excretion of irinotecan and its metabolite, SN-38, and increase the plasma concentration and toxicity. Organic anion transporters (e.g., OAT1, OAT3, and OAT4) are highly expressed on the renal proximal tubules and are involved in the renal elimination of methotrexate.[65] Nonsteroidal antiinflammatory drugs (e.g., salicylate, ibuprofen, and indomethacin), probenecid, and penicillin can inhibit these OATs and delay renal excretion of methotrexate, leading to severe and even life-threatening drug interactions, including bone-marrow suppression and acute renal failure.[66,67]

Coadministration of Complementary and Alternative Medicine

In recent years, interest in complementary and alternative medicine (CAM) has grown rapidly in the industrialized world.[68,69] No compelling clinical trial data support the use of CAM in children with cancer, and the potential interaction of CAM agents with conventional, possibly curative, treatment may be harmful. Families are more likely to use CAM for their child if a parent uses CAM, if the child has a poor prognosis, or if the parents are older and better educated.[68,69] Surveys within the past decade have estimated that CAM is used in 31% to 84% of pediatric oncology cases, and in many cases the treating clinician is unaware of the patient's use of CAM.[68,69] In addition to nonherbal therapies (e.g., hypnosis, guided imaginary, massage, and acupuncture), many children use herbal treatments, such as St. John's wort (*Hypericum perforatum*), garlic, and ginseng (*Panax ginseng*), in combination with allopathic therapies.[68,69] The risk of herb-drug interactions is a growing concern, and the need is increasing to understand possible adverse interactions. This concern is of particular relevance to pediatric oncology, because CAM use is more common in this group than in the general population.

During the past decade, a wealth of in vitro and in vivo evidence has shown that many herbal preparations interact extensively with drug-metabolizing enzymes and drug transporters. A number of clinically important interactions are now recognized, although causal relationships have not consistently been established and confirmatory studies in children are lacking. Most of the observed interactions suggest that the herbs inhibit or induce several isoforms of the CYP family, and concurrent use of some herbs with chemotherapy is likely to have serious clinical and toxicologic implications. An additional consideration for cancer chemotherapy is that herb-mediated induction or inhibition of phase I and II metabolic enzymes and ABC/SLC transporters may alter response. Therefore rigorous testing is urgently required to identify the pharmacokinetic interactions of anticancer drugs with widely used herbs. Drug-drug interaction potential has been investigated for only a limited number of herbs. For example, St. John's wort, melatonin, and whey protein are CYP450 inducers, and curcumin, goldenseal *(Hydrastis canadensis)*, and grapefruit juice *(Citrus paradise)* are strong inhibitors.[68,69] Milk thistle *(Silybum marianum)*, *Echinacea (Echinacea purpurea)*, saw palmetto, *Ginkgo biloba*, valerian, and green tea have showed no significant interactions. Because of the widespread use of herbal medicines in the United States, physicians should include it in their routine drug histories and review potential hazards with individual patients. PHARMACOGENETICS AND PHARMACOGENOMICS OF CHEMOTHERAPEUTIC AGENTS IN CHILDREN

Pharmacogenetics/pharmacogenomics investigates the influence of human genomic variation in drug response. Inherited (germline) or acquired (somatic) variation in genes encoding drug-metabolizing enzymes, drug receptors, drug transporters, and drug targets have all been shown to influence anticancer drug response in humans and they may also influence drug toxicity.[70]

A single nucleotide polymorphism (SNP) is defined as a single base change in a DNA sequence.[71] Unless it occurs in at least 1% of the population, it is considered a variant or a mutation. Accumulation of mutations during evolution, in concert with random selection, has made SNPs the most common form (about 90%) of genetic variation in the human genome.

The advent of pharmacogenomics was characterized by the passage from a candidate gene approach to a genome-wide approach. This advance was initially made possible by the international HapMap project, which included 270 samples from three geographic areas of genetic descent—African descent (Yoruban population); European descent (Center d'Etude du Polymorphisme Humain population), and Asian descent (Japanese and Han Chinese population)—and more than 2 million publicly available SNPs.[72] Subsequently, the "1000 Genomes Project" has provided the most detailed catalogue of human genetic variation. The recent development of next-generation sequencing technologies has allowed better coverage of all genetic variants.[73]

Advances in treatment have greatly improved the survival rates of children with cancer. However, the efficacy of therapy, as well as its short- and long-term adverse effects, can vary among patients, even when their chemotherapeutic or radiologic treatment is identical. Thus it is very important to identify inherited (germline) genomic variations that can alter the absorption, distribution, metabolism, and/or excretion of chemotherapeutic agents, thereby altering their effects and toxicities (Table 46-4).

Thiopurines

Thiopurines frequently used for the treatment of childhood ALL are 6-mercaptopurine and 6-thioguanine (see Table 46-1). As prodrugs, they require conversion to thioguanine nucleotides (TGNs) via the purine-salvage pathway, and 6-thioguanosine 5′-triphosphate (TGTP) and deoxy-TGTP are then incorporated into ribonucleic acid (RNA) or DNA, respectively (Fig. 46-6). The active DNA mismatch repair system identifies these base-pair mismatches and induces cell cycle arrest and apoptosis.[74,75] An alternative protein complex that includes high mobility group box 1 and 2 proteins, heat shock cognate protein 70 (HSC70), protein disulfide isomerase (ERp60), and glyceraldehyde 3-phosphate dehydrogenase trigger apoptosis when it detects changes in DNA structure caused by incorporation of nonnatural nucleosides.[76] Thiopurines are inactivated by methylation catalyzed by thiopurine methyltransferase (TPMT). The relation between *TPMT* polymorphisms and thiopurine efficacy and toxicity provides a well-established example of the

TABLE 46-4 Pharmacogenomics of Chemotherapeutic Agents Used for Pediatric Cancer

Agent	Genes Involved	Effects
Thiopurines	*TPMT*3A* (460 G>A and 719 A>G), *TPMT*3C* (719 A>G), and *TPMT*2* (238G>C)	Higher incidence of hematopoietic cell toxicities, secondary malignancies in ALL
6-mercaptopurine	*PACSIN2* (rs2413739, T allele)	Lower TPMT activity and higher incidence of severe gastrointestinal toxicity in ALL
6-thioguanine	*ITPA* (rs41320251, C>A)	Higher methylmercaptopurine nucleotides and higher incidence of febrile neutropenia when mercaptopurine dose was adjusted with *TPMT* genotype in ALL
Methotrexate	*SLC19A1* (G80A, AA or AG vs. GG)	Worse EFS and higher gastrointestinal toxicities in ALL
	SLC19A1 AA80 and positive *GSTM1*	Higher incidence of hepatotoxicity in ALL
	DHFR (G308A, AA or AG vs. GG) and *DHFR* *1b haplotype	Worse EFS in ALL
	TYMS (3/3 vs. 2/3 or 2/2)	Increased risk of hematologic relapse in ALL
	MTHFR (C677T, TT vs. CC)	Increased risk of relapse in ALL
	MTHFR (T677A1298 haplotype)	Lower EFS in ALL, especially in the presence of *TYMS* (3/3)
	MTHFD1 (A1958 variant, AA or GA vs. GG)	Lower EFS in ALL, especially in the presence of *TYMS* (3/3)
	SLCO1B1 (rs11045879 [T allele], rs4149081 [G allele], and rs4149056 [TT])	Higher methotrexate clearance and higher incidence of gastrointestinal toxicity in ALL
Glucocorticoids Prednisone Prednisolone	*NR3C1* (-627 AA vs. AG or GG, intron 2+646 CG or GG vs. CC, and 9b TT vs. CC or TC)	Worse EFS in ALL
Dexamethasone	*NR3C1* (1088 AG vs. AA)	Increased risk of hematologic relapse in ALL patients with *GSTM1* null genotype
	GSTT1 (*0/0 vs. *A/A)	Better early response to prednisone in ALL
	GSTP1 (codon105 Val/Val or Val/Ile vs. Ile/Ile, codon 114 Ala/Ala vs. Ala/Val or Val/Val)	Increased central nervous system relapse in ALL
	GSTM1 (null vs. normal)	Severe infection in ALL
	SNPs in *CNTNAP2, LEPR, CRHR1, NTAN1, SLC12A3, ALPL, BGLAP,* and *APOB*	Association with hypertension during remission-induction therapy in ALL
	ACP1 (rs 12714403 AA or AG vs. GG)	Higher incidence of symptomatic osteonecrosis in ALL
	TYMS (2/2 vs 3/3 or 2/3) and *VDR* (rs2228570, CC vs. TT or CT)	Higher incidence of osteonecrosis in ALL
	PAI-1 (rs6092, AA or GA vs. GG)	Higher incidence of osteonecrosis in ALL
Asparaginase		
Escherichia coli asparaginase	*ATF5* T1562C (TT or CT vs. CC)	Inferior EFS when treated with *Escherichia coli* asparaginase in ALL
PEG-asparaginase	SNPs in *ADSL, DARS, ASS1, DARS2, NARS2, ADSSL1*	Association with in vitro asparaginase sensitivity in ALL
Erwinia asparaginase	*GRIA1* (rs4958381, A allele vs. G allele)	Higher incidence of asparaginase hypersensitivity in ALL
Vincristine	*VDR* intron 8 (AA or AG vs. GG), *CYP3A5*3* (AA or AG vs. GG)	Increased peripheral neuropathy in ALL
	PMP22 duplication (Charcot-Marie-Tooth disease)	Increased peripheral neuropathy in ALL
Anthracycline		
Daunorubicin	*CBR3 V244M* (GG vs. GA or AA)	Increased cardiomyopathy, especially with anthracycline dose at 1-250 mg/m^2
Doxorubicin	*SLC28A3* (rs7853758, L461L)	Decreased risk of cardiotoxicity
Mitoxantrone	*ABCC1* (rs3743527TT, combination of rs3743527TT-rs246221TC/TT)	Increased cardiotoxicity in ALL
Idarubicin	*CAT* (rs10836235; c.66 + 78C > T, CC vs. TC)	Increased cardiotoxicity in ALL
Cytarabine	*SLC29A1* haplotype with −1345C>G, −1050G>A, or −706G>C	Associated with high hENT1 expression
	DCK −360G allele (GG or CG vs. CC)	Increased risk of mucositis after low-dose cytarabine in ALL
	CDA A79C (CC vs. AA or AC)	Higher postinduction treatment-related mortality in AML
	CDA G208A (GA or AA vs. GG)	Lower activity of CDA and increased sensitivity to cytarabine in ALL, AML, and NHL

TABLE 46-4 Pharmacogenomics of Chemotherapeutic Agents Used for Pediatric Cancer (Continued)

Agent	Genes Involved	Effects
Etoposide	*ABCB1* exon 26 (3435C>T, CC or CT or TT)	Higher clearance in patients with ALL who have prednisone pretreatment
	*CYP3A5*3* (AA vs. AG or GG) and *GSTP1* (313 A>G, AA vs. AG or GG)	Lower clearance in black patients with ALL who have prednisone pretreatment
	VDR intron 8 (GG vs. AG) and *VDR* Fok 1 (CC vs. CT or TT)	Higher clearance in black patients with ALL who do not have prednisone pretreatment
	UGT1A1 (7/7 vs. 6/7 or 6/6)	Lower clearance in black patients with ALL who do not have prednisone pretreatment
	SNPs in *AGPAT2, IL1B,* and *WNT5B*	Higher etoposide catechol AUC in black and white patients with ALL
	SNPs in *UVRAG, SEMA5A, SLC7A6,* and *PRMT7*	Association with etoposide cytotoxicity
		Association with etoposide cytotoxicity
	MDM2 309T>G	Decreased sensitivity to etoposide
Cyclophosphamide	*CYP2B6*4* (AG or GG vs. AA), recipient	Higher incidence of oral mucositis in patients with leukemia who received MSD HSCT
	*CYP2B6*2* (CT or TT vs. CC), recipient	Higher incidence of hemorrhagic cystitis in patients with leukemia who received MSD HSCT
	*CYP2B6*6* (GG vs. GT or TT), donor	Higher incidence of SOS in patients with leukemia who received MSD HSCT
	CYP2B6 rs3211371, R487C (Arginine), recipient	Reduced toxicity <100 days after allogeneic HSCT
	SOD2 rs4880, V16A (Valine), recipient	Higher overall toxicity after allogeneic HSCT
Platinum compounds Cisplatin Carboplatin Oxaliplatin	*ERCC2* Lys751Gln G allele (TG or GG vs. TT)	Poor tumor response and shorter EFS in patients with osteosarcoma treated with cisplatin
	GSTM3 (*B allele vs. *A allele)	Protective effect for cisplatin-induced ototoxicity in solid tumor and CNS malignancies
	GSTP1 (^{105}Val/^{105}Val vs. ^{105}Ile/^{105}Ile or ^{105}Ile/^{105}Val)	Protective effects in long-term cisplatin-induced hearing impairment in testicular cancer
	GSTM1 and *GSTT1* polymorphisms (≥1 null type vs. non-null type)	More cognitive impairment after therapy in children with medulloblastoma
	TPMT (rs12201199, A allele) and *COMT* (rs9332377, A allele)	Increased cisplatin-induced hearing loss in patients with solid tumor and CNS malignancies

potential clinical importance of pharmacogenomics (Fig. 46-7 and Table 46-4).[77-79] SNPs in the *TPMT* gene are associated with different inherited levels of TPMT enzyme activity.[80-83] One in approximately 400 white persons has profound TPMT deficiency resulting from inheritance of two nonfunctional variants of *TPMT*, 6% to 11% have intermediate activity by having heterozygous variants of *TPMT*, and 89% to 94% have normal activity (homozygous wild-type *TPMT*).[74,84,85] Ethnic differences exist in the frequency of occurrence of these variant alleles and thus in the frequency of TPMT deficiency. To date more than 20 *TPMT* variants have been identified, but three variants—*TPMT*3A* (460 G>A and 719 A>G), *TPMT*3C* (719 A>G), and *TPMT*2* (238 G>C)—account for more than 90% of inactivating alleles.[86,87]

The specific activity of TPMT determines the efficacy of thiopurine treatment and serves as an indirect indicator of hematologic toxicity.[88] At conventional thiopurine doses, patients with inherited TPMT deficiency accumulate excess intracellular concentrations of thioguanine nucleotides (TGN) especially in hematopoietic cells, predisposing them to moderate to severe hematologic toxicity depending on their deficiency status (i.e., heterozygous vs. homozygous).[77,89] In addition, several studies have found a relationship between low TPMT activity and secondary neoplasms, especially at high doses (e.g., mercaptopurine, 75 mg/m^2/day).[90,91] Patients with homozygous and heterozygous TPMT deficiency can be treated safely with appropriate adjustment of the thiopurine dosage.[92,93]

Because some patients with wild-type *TPMT* experience toxicities during mercaptopurine treatment, a genome-wide association study was performed to identify additional genetic determinants of thiopurine toxicity (see Table 46-4). In an analysis of a panel of human HapMap cell lines followed by validation in patients with ALL, the protein kinase C and casein kinase substrate in neurons–2 *(PACSIN2)* gene was among the top genes

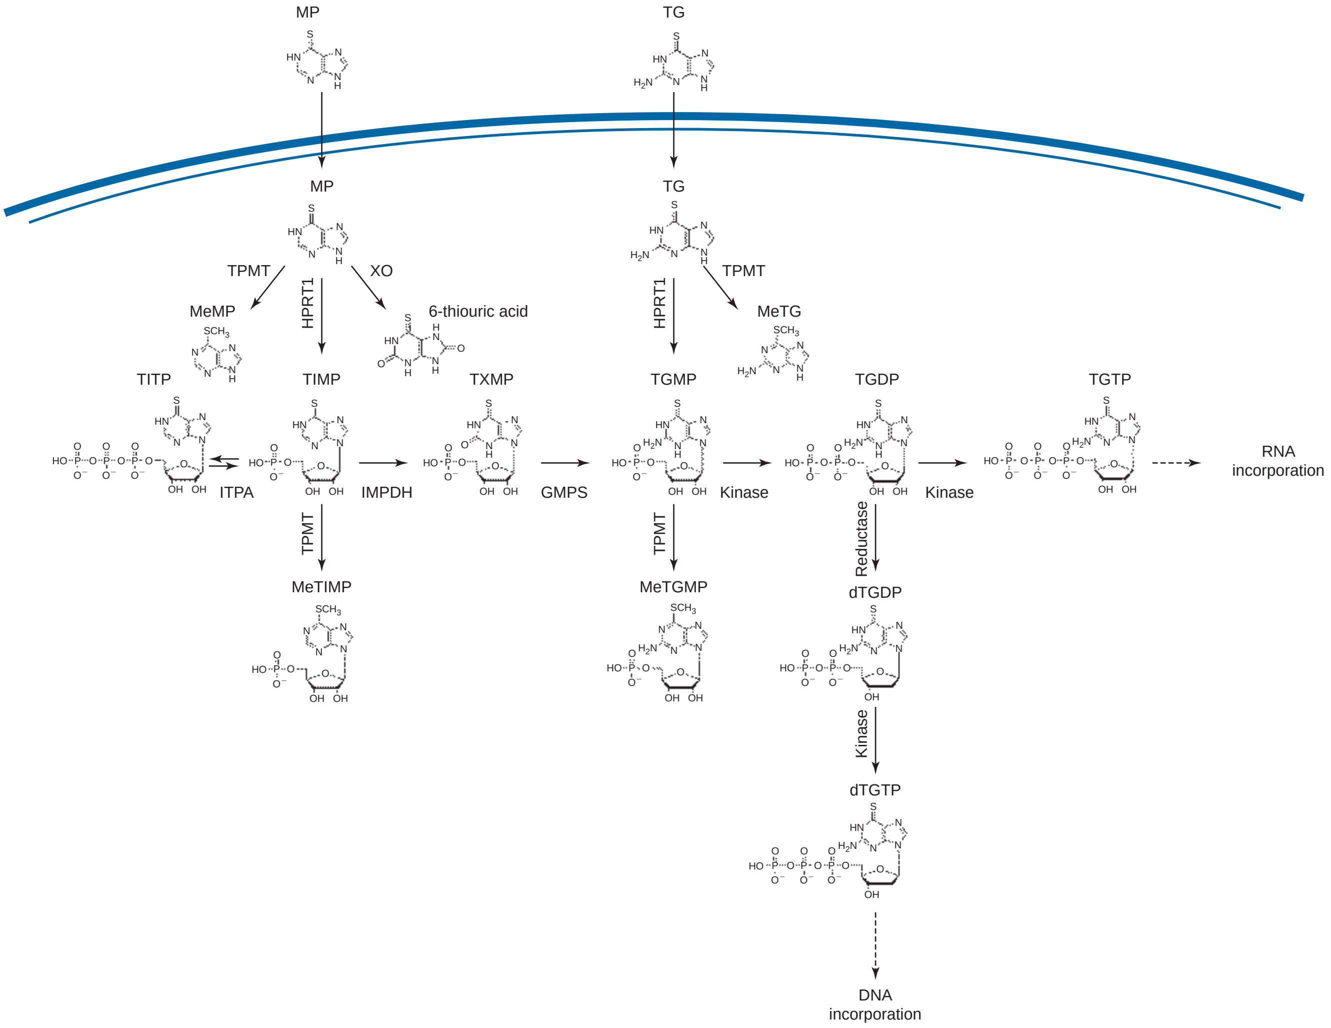

Figure 46-6 Metabolic pathways of 6-mercaptopurine and 6-thioguanine. 6-Mercaptopurine *(MP)* and 6-thioguanine *(TG)* are prodrugs that require conversion to thioguanine nucleotides (TGNs) via the purine-salvage pathway. The TGNs are incorporated into deoxyribonucleic acid *(DNA)* or ribonucleic acid *(RNA)*. Thiopurines are inactivated by thiopurine methyltransferase *(TPMT)* through catalytic methylation and by xanthine oxidase *(XO)*. Inosine triphosphate pyrophosphatase *(ITPA)* catalyzes the hydrolysis of thioinosine triphosphate *(TITP)* to 6-thioinosine 5′-monophosphate *(TIMP)*. *dTGDP,* Deoxy-6-thioguanosine 5′-diphosphate; *dTGTP,* deoxy-6-thioguanosine 5′-triphosphate; *GMPS,* guanosine monophosphate synthetase; *HPRT1,* hypoxanthine phosphoribosyltransferase 1; *IMPDH,* inosine-5′-monophosphate dehydrogenase; *Me,* S-methyl; *TGDP,* 6-thioguanosine 5′-diphosphate; *TGMP,* 6-thioguanosine 5′-monophosphate; *TGTP,* 6-thioguanosine 5′-triphosphate; *TXMP,* 6-thioxanthosine 5′-monophosphate.

identified, and the T allele of the *PACSIN2* SNP rs2413739 was significantly associated with lower TPMT activity and a higher incidence of severe gastrointestinal toxicity during consolidation therapy for ALL.[94] PACSIN2, also called syndapin II, has a role in various biologic processes, including endocytosis, cell-cycle control, and autophagy. PACSIN2 may influence TPMT activity by influencing *TPMT* messenger RNA levels and/or TPMT protein degradation. Furthermore an SNP (rs41320251, C>A) in the inosine triphosphate pyrophosphatase *(ITPA)* gene was associated with significantly higher accumulation of methylmercaptopurine nucleotides and a higher incidence of febrile neutropenia during ALL therapy in patients whose mercaptopurine doses had been individualized to the *TPMT* genotype.[95] These findings illustrate that even when treatment has been adjusted for the strongest genetic determinant of drug response, additional genetic variants may emerge as determinants of a drug's effects.

Methotrexate

Methotrexate is a folate analogue commonly used in the treatment of certain pediatric malignancies, including ALL and osteosarcoma (Fig. 46-8 and Table 46-1).[96] Cellular uptake is mediated mainly by the reduced folate carrier RFC1 (also known as SLC19A1).[97-99] In cells, cytosolic folylpolyglutamyl synthase converts methotrexate to methotrexate polyglutamates (MTXPGs) by adding as many as five glutamate residues. Methotrexate and MTXPG inhibit dihydrofolate reductase (DHFR), the enzyme responsible for conversion of dihydrofolate to its active form, tetrahydrofolate. In addition, MTXPG

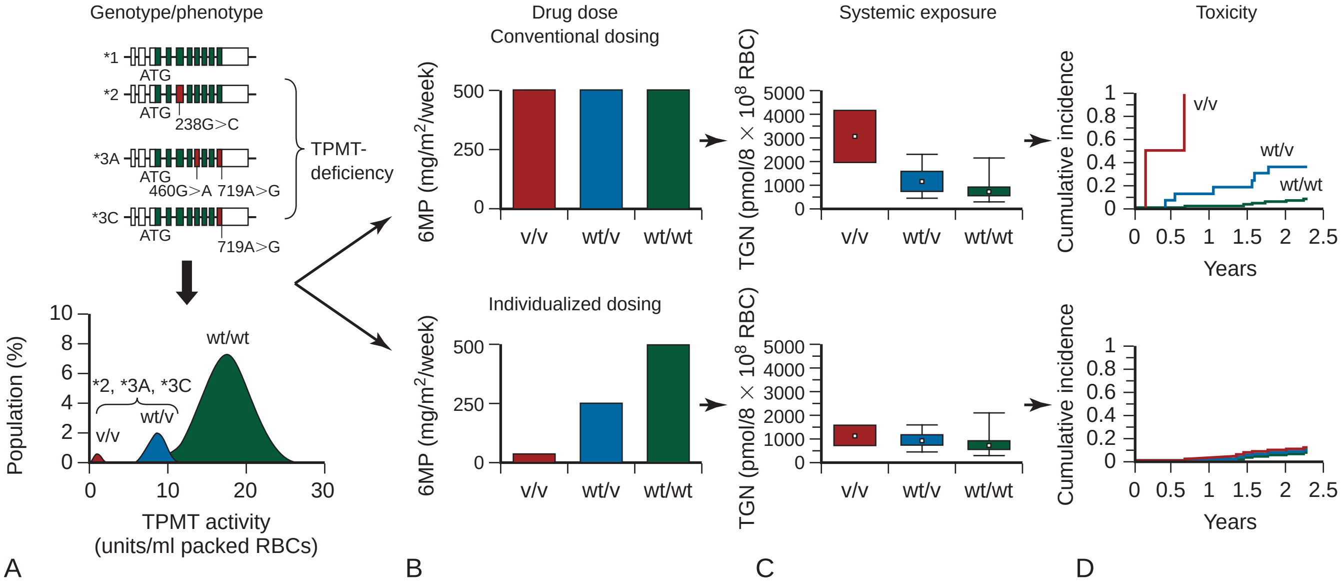

Figure 46-7 Polymorphisms in thiopurine methyltransferase and their effects on the pharmacogenetics of mercaptopurine toxicity. Wild-type thiopurine methyltransferase (*TPMT*1*) and the three predominant *TPMT* variant alleles (*TPMT*2*, *TPMT*3A*, and *TPMT*3C*) are shown (**A**). These changes cause autosomal codominant inheritance of TPMT activity in humans. The wild-type *(wt/wt)* enzyme is most active, homozygous variants *(v/v)* are least active, and the heterozygous wild-type/variant enzyme *(wt/v)* has intermediate activity. When mercaptopurine *(MP)* treatment is given to a cohort of patients, dosing can be conventional or individualized according the patient's genotype (**B**). When conventional doses of mercaptopurine are given, TPMT-deficient patients *(v/v)* have a systemic exposure to active thioguanine nucleotides *(TGN)* 10 times that of wild-type patients *(wt/wt)*, and heterozygous patients have TGN concentrations about two times that of wild-type patients (**C**). The higher concentrations of TGN cause a significantly higher frequency of hematopoietic toxicity (**D**). When doses specifically adjusted to the genotype are given in an individualized therapeutic regimen, similar cellular TGN concentrations are achieved in all patients, and all three TPMT phenotypes can be treated without acute toxicity. *RBC,* Red blood cell. *(Modified from Cheok MH, Evans WE: Acute lymphoblastic leukaemia: a model for the pharmacogenomics of cancer therapy.* Nat Rev Cancer *6:117–129, 2006.)*

inhibits thymidylate synthetase (TYMS), thereby blocking purine and thymidine synthesis, as well as DNA and RNA synthesis. MTXPG is not readily effluxed from cells, making its formation advantageous for anticancer effects of methotrexate. Other enzymes such as 5,10-methylenetetrahydrofolate reductase (MTHFR) and methylenetetrahydrofolate dehydrogenase–1 (MTHFD1) are also key elements in folate metabolism and in methotrexate effects.[100,101] MTHFR catalyzes the reduction of 5,10-methylenetetrahydrofolate to 5-methyltetrahydrofolate, a cosubstrate of homocysteine remethylation to methionine, and MTHFD1 catalyzes interconversion of 1-carbon derivatives of tetrahydrofolate, which are substrates for methionine, thymidylate, and de novo purine synthesis. MTXPG can be degraded via cleavage by lysosomal γ-glutamyl hydrolase. Several transporters (e.g., ABCG2, ABCC2, OATP1B1 [SLCO1B1], OAT1, OAT3, and OAT4) also participate in methotrexate clearance.

Interpatient variability in the efficacy and toxicity of methotrexate treatment is associated with genetic variations in methotrexate metabolic pathways (see Table 46-4). The G80A polymorphism of *SLC19A1* replaces Arg with His at position 27 of the major methotrexate transporter RFC1 (encoded by *SLC19A1*). ALL patients with the A80 variant had lower event-free survival estimates than did those with the GG genotype.[102,103] However, this association has not been widely replicated, and patients homozygous for A80 had higher plasma levels of methotrexate than the other genotype groups; the mechanism by which this SNP might confer a worse prognosis is not clear.[103] In other studies, the G80A *SLC19A1* genotype was associated with a substantially higher incidence of gastrointestinal toxicity,[104] and patients with AA80 and positive *GSTM1* (glutathione S-transferase mu–1) had a higher incidence of hepatotoxicity.[105] Patients with Down syndrome experience greater methotrexate toxicity, requiring dose reduction and early leucovorin rescue.[106] This toxicity may partly reflect enhanced intracellular uptake of methotrexate, because *SLC19A1* is located on chromosome 21 and thus three copies are present in all cells of persons with Down syndrome, although other mechanisms, such as enhanced methotrexate polyglutamination and reduced folate depletion, may also be involved.

Altered levels of DHFR expression have been found in patients with relapsed ALL and in ALL cells with a methotrexate-resistant phenotype.[107,108] Genetic variations in both a major promoter and a noncoding minor transcript region of *DHFR* have been identified.[109] Patients with ALL who had an A allele of the G308A polymorphism and the *1b haplotype of *DHFR* had a significantly poorer outcome because of increased DHFR expression.

The promoter region of the *TYMS* gene exhibits a genetic polymorphism, having either two or three 28-base-pair tandem repeat sequences.[110] *TYMS* (3/3) was associated with greater TYMS expression and a

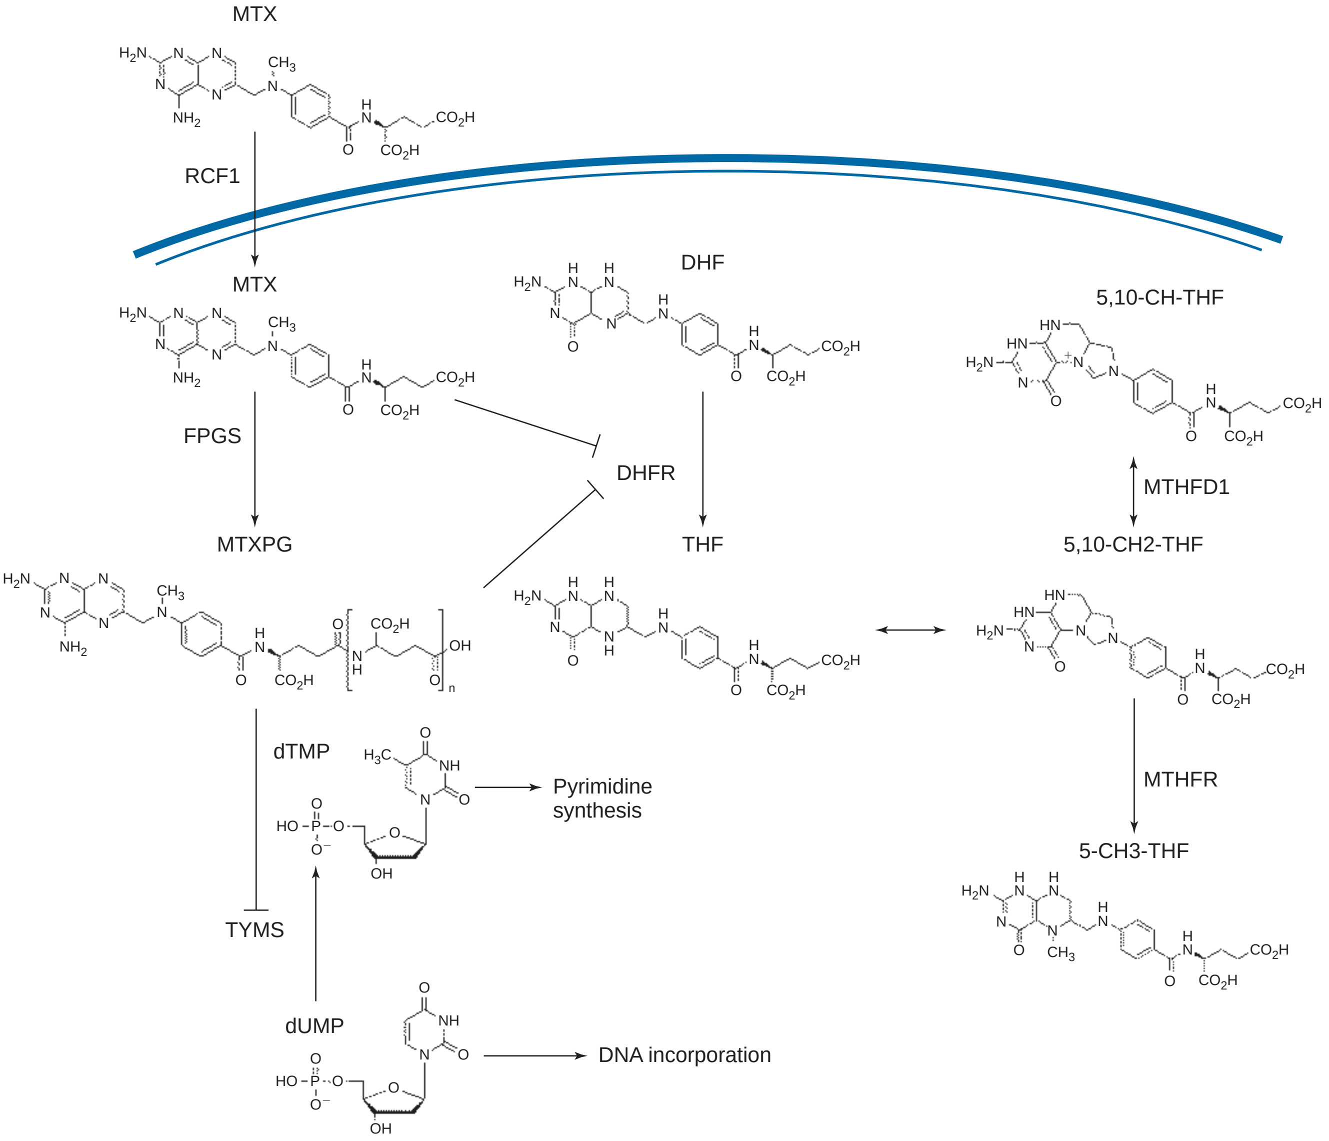

Figure 46-8 Metabolic pathways of methotrexate. Cellular uptake is mediated mainly by reduced folate carrier–1 *(RFC1)*. Within cells, cytosolic folylpolyglutamyl synthase *(FPGS)* converts methotrexate to methotrexate polyglutamates *(MTXPGs)* by adding glutamate residues. Methotrexate *(MTX)* and MTXPGs inhibit dihydrofolate reductase *(DHFR)*, the enzyme responsible for conversion of dihydrofolate *(DHF)*, to its active form, tetrahydrofolate *(THF)*. In addition, MTXPGs inhibit thymidylate synthetase *(TYMS)*, thereby blocking purine and thymidine synthesis, as well as deoxyribonucleic acid *(DNA)* and ribonucleic acid synthesis. 5,10-methylenetetrahydrofolate reductase *(MTHFR)* and methylenetetrahydrofolate dehydrogenase 1 *(MTHFD1)* are also key elements in folate metabolism and in methotrexate effects. *5,10-CH-THF,* 5,10-methenyltetrahydrofolate; *5,10-CH2-THF,* 5,10-methylenetetrahydrofolate; *5-CH3-THF,* 5-methyltetrahydrofolate; *dTMP,* deoxythymidine monophosphate; *dUMP,* deoxyuridine monophosphate.

greater risk of hematologic relapse of ALL than was observed in children with a 2/2 or 2/3 genotype, possibly implicating resistance to methotrexate, which targets this enzyme.[111,112]

Polymorphisms in the *MTHFR* gene, such as C677T and A1298C, which result in reduced enzymatic activity, have been implicated in the response to methotrexate treatment.[113-115] The *MTHFR* C677T polymorphism is a common genetic variant, and enzyme activity is reduced by 70% in patients with the homozygous TT polymorphism, conferring a greater risk of relapse in children with ALL.[116,117] Patients with either the *MTHFR* T677A1298 haplotype or the *MTHFD1* A1958 variant also had a lower rate of event-free survival, which became more evident in the presence of *TYMS* (3/3).[100]

A genome-wide analysis has identified common inherited variations in *SLCO1B1,* encoding OATP1B1, as important determinants of methotrexate pharmacokinetics and clinical effects.[118] Two SNPs, rs11045879 and rs4149081, were in linkage disequilibrium with each other and with the functional polymorphism T521C (rs4149056). These SNPs were associated with methotrexate clearance and gastrointestinal toxicity. The association of *SLCO1B1* SNP rs4149056 with methotrexate clearance was further validated in five different treatment regimens.[119] Of note, rare genetic variants of the

SLCO1B1 gene have been shown to have a greater impact on methotrexate clearance than common variants and to contribute to the inherited basis of methotrexate clearance and toxicity.[120]

Glucocorticoids

Glucocorticoids (prednisone or prednisolone and dexamethasone) are important components of ALL treatment (see Table 46-1). Glucocorticoids diffuse into the cell and bind to the glucocorticoid receptor, leading to its translocation into the nucleus.[121-123] In the nucleus, the glucocorticoid receptor transactivates or transrepresses glucocorticoid-responsive genes,[124] leading to inhibition of cytokine production, alteration of oncogene expression, cell-cycle arrest, and apoptosis.[125] Glucocorticoids can be metabolized by CYP450 enzymes (mainly CYP3A4) and glutathione-*S*-transferases (GSTs) and are transported by ABCB1.[126-129]

Sensitivity to glucocorticoid therapy is variable among patients, both in efficacy and the prevalence and severity of adverse effects. Numerous polymorphic sites in the glucocorticoid receptor gene (*NR3C1*) are described as being associated with prognosis (see Table 46-4).[130] Polymorphisms −627A/G, intron 2 +646C/G, and 9bT/C of *NR3C1* have each been associated with event-free survival in childhood ALL.[131] The *NR3C1* AG genotype (1088A>G) showed a greater association with hematologic relapse than did the *NR3C1* AA genotype among children with the *GSTM1*-null genotype.[111] Association between polymorphisms of the phase II enzyme GST and prognosis has also been reported. A deletion polymorphism in glutathione-*S*-transferase theta–1 *(GSTT1)* modulates the early response to glucocorticoids in childhood ALL; patients with *GSTT1**0/0 had a better early response to prednisone than did patients with *GSTT1**A/A.[132] Polymorphisms in glutathione-*S*-transferase pi–1 *(GSTP1)* codon 105 (Ile/Val) and codon 114 (Ala/Val) were associated predominantly with CNS relapse.[133]

The acute and late adverse effects associated with glucocorticoids include hypertension, infection, and osteonecrosis. Among 203 candidate polymorphisms, those in eight genes (*CNTNAP2* [contactin-associated protein-like–2], *LEPR* [leptin receptor], *CRHR1* [corticotropin releasing hormone receptor–1], *NTAN1* [N-terminal asparagine amidase], *SLC12A3*, *ALPL* [alkaline phosphatase, liver/bone/kidney], *BGLAP* [bone gamma-carboxyglutamate (gla) protein], and *APOB* [apolipoprotein B]) were associated with hypertension during remission-induction therapy (prednisone, 40 mg/m^2/day for 28 days) for childhood ALL.[134] In another candidate gene study that included *NR3C1*, *ABCB1*, *GSTM1*, *GSTP1*, *GSTT1*, and interleukin 10 *(IL10)* genes, the *GSTM1*-null genotype was associated with severe infections.[135] Glucocorticoid-induced osteonecrosis causes severe pain, limited range of motion of joints, and eventual joint destruction and mechanical failure because of compromised bone vascularization, demineralization, and trabecular thinning.[136] Clinically, older age, greater treatment intensity, lower serum albumin levels, higher cholesterol, and low dexamethasone clearance rates were important prognostic factors for osteonecrosis.[137,138,139,140,141,142] Polymorphisms (AA/AG) in acid phosphatase–1, soluble *(ACP1;* e.g., rs12714403), which regulates lipid levels and osteoblast differentiation, were associated with a greater risk of osteonecrosis and with lower albumin and higher cholesterol concentrations compared with those in patients with the GG genotype.[141] In addition, variants in *TYMS* (enhancer 2-repeat allele), vitamin D (1,25-dihydroxyvitamin D3) receptor *(VDR)* Fok I (rs2228570), and plasminogen activator inhibitor–1 *(PAI1;* rs6092) have been found to be associated with a higher incidence of osteonecrosis.[137,143]

Asparaginase

Asparaginase catalyzes the hydrolysis of asparagine to aspartic acid and ammonia (see Table 46-1). ALL cells have a low level of asparagine synthetase (ASNS) and are therefore dependent on external sources of asparagine.[144,145] Depletion of circulating endogenous asparagine by asparaginase therapy selectively kills leukemic cells by decreasing their protein synthesis. Three different formulations of asparaginase are available: native asparaginase derived from *Escherichia coli* (*E. coli* asparaginase); a pegylated form of the native *E. coli* asparaginase (polyethylene glycol [PEG] asparaginase); and asparaginase isolated from *Erwinia chrysanthemi* (*Erwinia* asparaginase).[146,147] The different asparaginase preparations have different pharmacokinetic properties, and thus the dosing schedule of each preparation is adjusted based on the half-life of the preparation; serum asparaginase concentrations at or above 0.1 international units/mL are believed to deplete asparagine levels to below the limit of detection.[148]

Asparaginase resistance appears to be caused by various mechanisms, and ASNS plays a variable functional role (see Table 46-4).[149-152] An analysis of 14 polymorphisms in the regulatory and coding regions of *ASNS*, activating transcription factor–5 *(ATF5)*, and argininosuccinate synthase–1 *(ASS1)* genes showed that *ATF5* T1562C was associated with lower event-free survival rates in patients with ALL who were treated with *E. coli* native asparaginase.[153] T1562 was associated with greater *ATF5* promoter activity, which may increase ASNS expression and lead to worse outcome. In a genome-wide study seeking to identify determinants of asparaginase sensitivity in lymphoblastoid HapMap cell lines and patient-derived ALL cells, the aspartate metabolic pathway was the most overrepresented.[154] SNPs primarily involved in this pathway included those in adenylosuccinate lyase *(ADSL)*, aspartyl-tRNA synthetase *(DARS)*, *ASS1*, *DARS2*, asparaginyl-tRNA synthetase–2 *(NARS2)*, and adenylosuccinate synthase-like–1 *(ADSSL1)*.

Asparaginase may be associated with adverse effects, including hypersensitivity, pancreatitis, hyperglycemia, and thrombosis.[155-158] Asparaginase hypersensitivity can lead to antibody formation, which is more commonly observed with native *E. coli* asparaginase than with PEG asparaginase.[159,160] Antibody formation was related to low systemic exposure to asparaginase and even to higher systemic clearance of dexamethasone.[161,162] A genome-wide association approach identified variations in the glutamate receptor, ionotropic, AMPA1 *(GRIA1)* gene, especially SNP rs4958381, as being associated with the risk of hypersensitivity to asparaginase among children with ALL.[163]

Vincristine

Vincristine is a natural alkaloid isolated from *Catharanthus roseus* (the Madagascar periwinkle) and is widely used in the treatment of both hematologic and solid malignancies (see Table 46-1).[164] Vincristine interferes with microtubule formation and mitotic spindle dynamics by interacting specifically with β-tubulin, causing mitotic arrest and cell death.[165] Vincristine is metabolized by CYP3A4 and CYP3A5 in the liver, mainly forming a secondary amine, M1 metabolite.[166-168] Vincristine appears to be exported from cells by ABCB1, ABCC1, ABCC2, and ABCC10.[169-173]

Vincristine is associated with a dose-limiting peripheral neurotoxicity, and several factors may influence its incidence and severity (Table 46-4). For example, underlying neuropathy (e.g., Charcot-Marie-Tooth disease [especially with duplication of peripheral myelin protein–22 *(PMP22)*] and Guillain-Barré syndrome) or myopathy (e.g., muscular dystrophy) and malnutrition have been reported to be associated with greater vincristine neuropathy.[165] The mechanism of vincristine-induced peripheral neuropathy has not been fully elucidated. *CYP3A5* is highly polymorphic, with variants including *CYP3A5*3*, *CYP3A5*6*, and *CYP3A5*7*.[168,174,175] The association of genetic polymorphisms with vincristine-induced neurotoxicity appears to be inconsistent and may be influenced by the treatment context (e.g., disease and concomitant therapy). VDR regulates CYP3A4, CYP3A5, and ABCB1.[176] Variants in *VDR* intron 8 (AA or AG) and *CYP3A5*3* (AA or AG) were associated with a higher incidence of peripheral neurotoxicity during continuation therapy in children with ALL,[104] and children with ALL who express a functional CYP3A5 experienced less vincristine-induced peripheral neuropathy.[177] In another study, however, patients with the *CYP3A4*1B* and *CYP3A5*3* variant genotypes had a decreased risk of peripheral neuropathy that was statistically significant in a univariate analysis but not in a multivariate analysis.[178] Expression of the efflux transporters ABCB1 and ABCC1 in cancer cells has been reported to be associated with reduced accumulation of, and in vitro resistance to, vincristine.[179] However, a retrospective analysis of children with ALL showed no association between the *ABCB1* SNPs C3435T and G2677T and vincristine pharmacokinetics or toxicity.[180] Thus additional studies are needed to identify genomic variations associated with vincristine neurotoxicity and/or cancer cell resistance.

Anthracyclines

The anthracyclines (e.g., daunorubicin, doxorubicin, mitoxantrone, and idarubicin) are antibiotic chemotherapeutic agents used for both hematologic and solid malignancies (Table 46-1).[181,182] The antitumor activity of anthracyclines is attributed to their ability to intercalate between base pairs of DNA and inhibit the topoisomerase II enzyme, preventing the relaxing of supercoiled DNA and thus blocking transcription and replication.[183-185] Daunorubicin differs from doxorubicin by the substitution of a hydroxyl group for a hydrogen atom in the acetyl radical.[186] Although anthracyclines are considered to enter the cell via passive diffusion, transport proteins are also involved.[187,188] Within cells, the anthracyclines are substrates for the ABC efflux transporters. The mechanism of resistance to anthracyclines can involve increased efflux via ABCB1, ABCC1, and/or ABCG2.[189-191] To overcome this resistance, functional modulation of the ABC drug transporters has been investigated, mainly in adults.[192,193]

The cumulative dose of anthracyclines is limited by their selective toxicity to cardiomyocytes, which are vulnerable to free radical damage due to low activity of antioxidant enzymes. Free oxygen radicals cause DNA damage and mitochondrial dysfunction.[194] Daunorubicin and doxorubicin are metabolized to the more cardiotoxic hydroxyl derivatives, daunorubicinol and doxorubicinol, respectively, by the myocardial cytosolic carbonyl reductases (CBRs) and aldo-keto reductases. In humans, two monomeric CBRs (CBR1 and CBR3) are encoded by genes located on chromosome 21.[195,196] The *CBR3* V244M polymorphism showed a trend toward association with the risk of congestive heart failure (see Table 46-4).[197] Although the risk of cardiomyopathy generally increases with cumulative doses of anthracycline greater than 250 mg/m^2, a homozygous G allele in *CBR3* V244M increases the risk of cardiomyopathy even at low to moderate cumulative doses (1 to 250 mg/m^2), suggesting that no safe dosage exists for patients with this SNP (Fig. 46-9).[198] In a study of 2977 SNPs in 220 key drug biotransformation genes, it was found that the synonymous coding variant rs7853758 (L461L) within the *SLC28A3* gene had a significantly protective effect

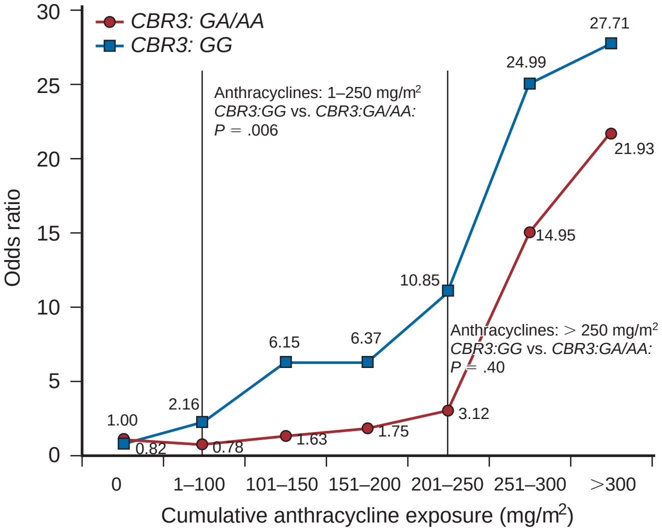

Figure 46-9 Dose-response relationship between cumulative anthracycline exposure and risk of cardiomyopathy, stratified by patients' carbonyl reductase–3 *(CBR3)* genotype (*CBR3*:GG or *CBR3*:GA/AA). Patients with the *CBR3*:GA/AA genotype who were not exposed to anthracyclines served as the reference group. Magnitude of risk is expressed as odds ratio. *(From Blanco JG, Sun CL, Landier W, et al: Anthracycline-related cardiomyopathy after childhood cancer: role of polymorphisms in carbonyl reductase genes—a report from the Children's Oncology Group.* J Clin Oncol *30:1415–1421, 2012.)*

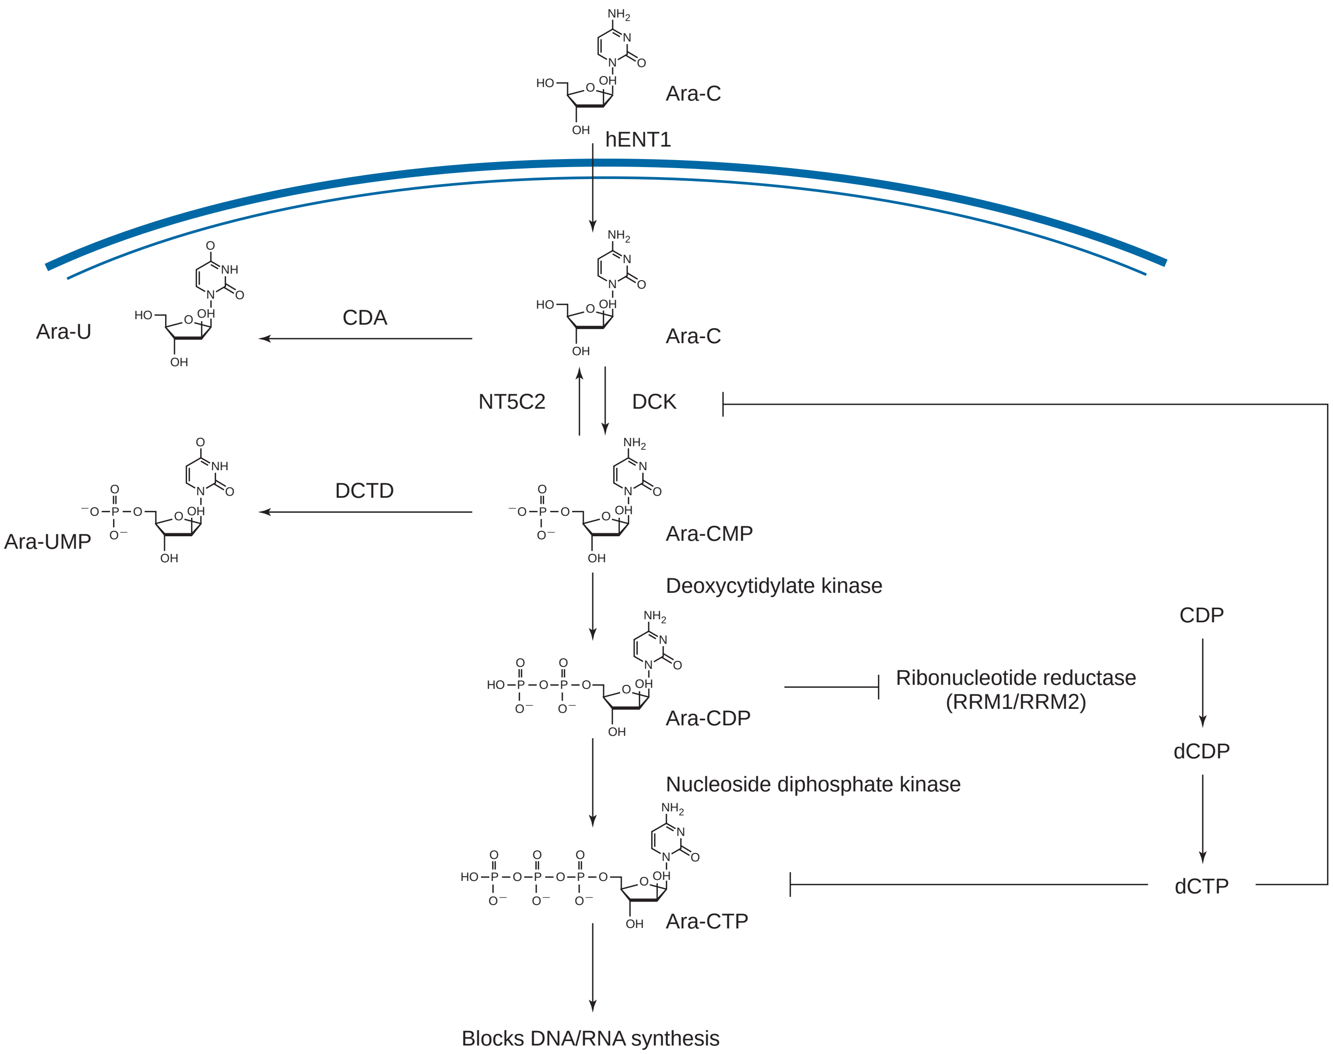

Figure 46-10 Metabolic pathways of cytarabine. Cytarabine *(Ara-C)* is transported through the cell membrane by the human equilibrative nucleoside transporter *(hENT1)*. It is first phosphorylated by deoxycytidine kinase *(DCK)* to form arabinosylcytosine 5′-monophosphate *(ara-CMP)*, which is then phosphorylated by deoxycytidylate kinase to arabinosylcytosine 5′-diphosphate *(ara-CDP)* and converted by nucleoside diphosphate kinase to the active arabinosylcytosine 5′-triphosphate *(ara-CTP)*. Ara-CMP can be dephosphorylated back to ara-C by 5′-nucleotidase *(NT5C2)*. Both ara-C and ara-CMP can be converted to inactive forms (uracil arabinoside *[ara-U]* and uracil arabinoside monophosphate *[ara-UMP]*) by cytidine deaminase *(CDA)* and deoxycytidylate deaminase *(DCTD)*, respectively. Larger intracellular pools of deoxycytidine triphosphate *(dCTP)*, which is regulated by ribonucleotide reductase, can compete with deoxyribonucleic acid *(DNA)* incorporation of ara-CTP and inhibit DCK activity. *CDP,* Cytidine diphosphate; *dCDP,* deoxycytidine diphosphate; *RNA,* ribonucleic acid; *RRM,* ribonucleotide reductase M.

against anthracycline-induced cardiotoxicity.[199] Risk and protective variants in other genes included *SLC28A1* and several ABC transporters (*ABCB1*, *ABCB4*, and *ABCC1*). Combination of these multiple variants into a single prediction model that included clinical risk factors was able to identify patients at high risk of anthracycline cardiotoxicity. Other studies found cardiotoxicity to be associated with the *ABCC1* rs3743527TT genotype and the rs3743527TT-rs246221TC/TT genotype combination[200] and with CC homozygosity at rs10836235 of the catalase gene (*CAT* c.66 + 78C > T) in childhood ALL.[201]

Cytarabine

Cytarabine (cytosine arabinoside, ara-C, 1-β-arabinofura nosylcytosine), is one of the most effective chemotherapeutic agents for treatment of AML and ALL (see Table 46-1). Ara-C is a deoxynucleoside analogue and is transported through the cell membrane by the human equilibrative nucleoside transporter (hENT1/SLC29A1) (Fig. 46-10). Within the cell, ara-C undergoes a series of phosphorylations. It is first phosphorylated by deoxycytidine kinase (DCK) to form arabinosylcytosine 5′-monophosphate (ara-CMP), which is then phosphorylated by pyrimidine kinases to the active 5′-triphosphate derivative, arabinosylcytosine 5′-triphosphate (ara-CTP).[202-204] Ara-CTP is incorporated into DNA and causes chain termination, blocking DNA and RNA synthesis.[205,206] Ara-CMP can be dephosphorylated back to ara-C by 5′-nucleotidase (NT5C2). Both ara-C and ara-CMP can be converted into inactive forms (uracil arabinoside [ara-U] and uracil arabinoside monophosphate [ara-UMP]) by cytidine deaminase (CDA) and deoxycytidylate deaminase, respectively.[207] Insufficient cellular uptake of ara-C caused by a low level or activity of hENT1 reduce levels of activating enzymes (primarily DCK), and increased levels of inactivating enzymes (e.g., NT5C2 and CDA) reduce the level of ara-CTP.[208,209] Further, larger intracellular pools of deoxycytidine triphosphate (dCTP), which is regulated by ribonucleotide reductase, can compete with DNA incorporation of ara-CTP and inhibit DCK activity.

The expression of hENT1 appeared to be related to the cytarabine sensitivity of childhood AML cells in vitro,[210] and haplotypes including −1345C>G, −1050G>A, and −706G>C of the *SLC29A1* promoter region were related to higher hENT1 expression, which may alter ara-C chemosensitivity (see Table 46-4).[211]

DCK activity and expression vary widely in normal and malignant cells but may be related to ara-C sensitivity and patient survival.[212] Polymorphisms in the *DCK* gene differ between races; SNPs in the 5′ regulatory region (−201C>T and −360C>G) are common in the Chinese population and less common in Caucasians.[213] Adult Chinese patients with AML who have the −360CG/−201CT and −360GG/−201TT compound genotype had higher levels of DCK mRNA and a greater response to chemotherapy than patients with the −360CC/−201CC compound genotype.[214] The *DCK* −360G allele was found to increase the risk of mucositis after exposure to low-dose cytarabine in Asian children with ALL.[215]

Analysis of functional SNPs in human *CDA* led to the identification of three polymorphisms (A79C, G208A, and T435C) in the coding region. Analysis of the impact of the *CDA* A79C genotype on therapy outcomes in children with AML showed that postinduction treatment-related mortality was significantly greater in patients with the CC genotype, which is associated with low CDA activity.[216] The G208A polymorphism results in an alanine to threonine substitution (A70T) within the conserved catalytic domain, and the 208A genotype was associated with lower CDA activity and greater sensitivity to ara-C in pediatric leukemia cells.[217] Another polymorphism in the *CDA* promoter, SNP C-451T, reduces the expression level and enzymatic activity of CDA.[218] *CDA* SNP C-451T was found to be a significant, independent predictor of survival in adult AML, in which the TT genotype predicted higher risk.

Imatinib Mesylate

Imatinib mesylate (Gleevec) or 4-[(4-methyl-1-piperazinyl)methyl]-N-[4-methyl-3-[[4-(3-pyridinyl)-2-pyrimidinyl]amino]-phenyl] benzamide methanesulfonate is a breakpoint cluster region-Abelson (BCR-ABL) tyrosine kinase inhibitor commonly used for the treatment of chronic myeloid leukemia and Philadelphia chromosome–positive ALL (see Table 46-1).[219-222] Imatinib is metabolized to the active metabolite N-desmethyl-imatinib by CYP3A4; CYP3A5 and other CYP enzymes (e.g., CYP2D6, CYP2C9, and CYP2C19) play minor roles.[223] Imatinib is a substrate of the ABC transporters ABCB1 and ABCG2. It is bound to plasma proteins, predominantly albumin and α1-acid glycoprotein.[224] Pharmacogenetic studies of imatinib, conducted mainly in adults, implicated SNPs in *ABCB1* (positions 1236, 2677, and 3435) and *ABCG2* (rs2231142) as affecting drug response.[225-228] Authors of a study in children with solid tumors and adults with gastrointestinal stromal tumors investigated the effect of several demographic, biologic, and pharmacogenetic covariates on the disposition of imatinib.[229] Morphologic and biologic characteristics (i.e., body weight, albumin, and plasma α1-acid glycoprotein levels) influenced imatinib pharmacokinetics more strongly than pharmacogenetics. Somatic DNA changes or selection of subclones with preexisting mutations in the tyrosine kinases targeted by imatinib are the predominant genetic mechanisms underlying imatinib resistance.[230]

Etoposide

Etoposide (VP-16), 4′-demethylepipodophyllotoxin-9-(4,6-O-ethylidene)-β-D-glucopyranoside, is a semisynthetic derivative of podophyllotoxin that inhibits DNA topoisomerase II and is used for the treatment of several malignancies, including AML and solid tumors (see Table 46-1).[231] Etoposide is metabolized to a catechol etoposide through an O-demethylation reaction catalyzed mainly by CYP3A4 and CYP3A5 and to a minor degree by CYP1A2 and CYP2E1.[232,233] CYP3A4 and CYP3A5 expression is regulated in part by the VDR.[176] Etoposide catechol metabolite binds covalently to DNA and cellular proteins and displays intrinsic cytotoxic properties.[234] Etoposide metabolites can be conjugated to glutathione by GSTs and can be glucuronidated by the uridine diphosphate–glucuronosyltransferase 1A1 *(UGT1A1)* gene.[235] Etoposide and its metabolites are substrates for the efflux transporters ABCB1, ABCC1, and ABCC2 and for the influx transporter OCTN2.[236,237] In addition, the pharmacokinetics of etoposide in children are reported to be influenced by other factors, including body weight and excessive urinary carnitine loss.[237,238]

Genetic variants that contribute to etoposide metabolism and etoposide-induced cytotoxicity have been identified (see Table 46-4). A study in children with ALL showed that the pharmacokinetics of etoposide and its catechol metabolite are related to polymorphisms in *CYP3A5*, *ABCB1*, *GSTP1*, *UGT1A1*, and *VDR* in a manner influenced by race and by prednisone use.[239] Etoposide clearance rates were significantly higher in patients who had recently received prednisone, which can modulate expressions of CYP3A and ABCB1. The *ABCB1* exon 26 (3435C>T) CC genotype was associated with higher etoposide clearance for patients on day 29 of remission-induction therapy, after 28 days of prednisone treatment, and the *CYP3A5*3* AA and *GSTP1* (313 A>G) AA genotypes predicted lower clearance in black patients. At week 54 of continuation treatment without preceding prednisone treatment, the *VDR* intron 8 GG and *VDR* Fok 1 CC genotypes predicted higher etoposide clearance, and *UGT1A1* 7/7 predicted lower clearance, in black patients. The *UGT1A1 7/7* genotype predicted higher etoposide catechol AUC in both black and white patients.

A genome-wide study using the HapMap human lymphoblastoid cell lines identified 63 genetic variants that contribute to interindividual variation in etoposide cytotoxicity.[240] These variants included genes previously reported to be associated with carcinogenesis and sensitivity to etoposide (e.g., 1-acylglycerol-3-phosphate O-acyltransferase–2 *[AGPAT2]*, interleukin-1 beta *[IL1B]*, and wingless-type MMTV integration site family, member 5B *[WNT5B]*) and genes not yet known to be associated with sensitivity to etoposide. The influence of heritable genetic variation on etoposide cytotoxicity was confirmed by the identification of additional genomic regions and SNPs in *UVRAG* (UV radiation resistance–associated), *SEMA5A* (sema domain, seven thrombospondin repeats [type 1 and type 1-like], transmembrane domain [TM] and short cytoplasmic domain, [semaphorin] 5A), *SLC7A6*, and *PRMT7* (protein arginine methyltransferase–7), which may also be associated with adverse effects, including myelosuppression, therapy-related leukemia, and neurotoxicity.[241] Cell lines homozygous for the *MDM2* (murine double minute 2) SNP309 T to G change in the promoter region showed a lower response to etoposide that was attributable, at least in part, to the lower expression of topoisomerase II.[242]

Cyclophosphamide

Cyclophosphamide is an alkylating agent widely used in the treatment of childhood cancers, including leukemia, lymphoma, neuroblastoma, rhabdomyosarcoma, and brain tumor (Table 46-1). Cyclophosphamide is a prodrug first metabolized into 4-hydroxycyclophosphamide (4-OHCP) in the liver, which is mediated by CYP2B6, CYP2C9, and CYP3A4.[243,244] 4-OHCP exists in equilibrium with the aldophosphamide, which spontaneously degrades to the active DNA-alkylating agent phosphoramide mustard and to acrolein. Cyclophosphamide and 4-OHCP can be transformed to the inactive metabolites dechloroethylcyclophosphamide and 4 keto-cyclophosphamide, respectively, by CYP3A4 and CYP3A5.[243,245] Cyclophosphamide metabolites are detoxified by aldehyde dehydrogenase (ALDH) enzymes (ALDH1A1 and ALDH3A1) and the glutathione-*S*-transferase enzyme system (GSTP1 and glutathione-S-transferase alpha–1 [GSTA1]).[246]

The adverse effects of cyclophosphamide include cardiotoxicity, nephrotoxicity, and hemorrhagic cystitis, but these effects vary among patients (see Table 46-4). In children and adults with leukemia who received human leukocyte antigen–identical sibling-donor hematopoietic stem cell transplants, recipient CYP2B6*4 (AG or GG), recipient CYP2B6*2 (CT or TT), and donor CYP2B6*6 (GG) were associated with oral mucositis, hemorrhagic cystitis, and hepatic sinusoidal obstruction syndrome, respectively.[247] Another study showed that CYP2B6 rs3211371 R487C, which inhibits the activation of cyclophosphamide, was significantly associated with reduced toxicity less than 100 days after transplantation.[248] Superoxide dismutase–2 (SOD2) is a mitochondrial enzyme that converts endogenous toxic superoxides to hydrogen peroxide, and the valine variant has lower enzymatic activity. In *SOD2* rs4880 V16A polymorphism, the valine allele was associated with significantly greater overall toxicity.

In adult women with breast cancer who were treated with cyclophosphamide, women with at least 1 *GSTP1* (rs1695) variant G allele had a lower risk of neutropenia and leukopenia than those with the AA genotype,[249] and women with *GSTA1**B/*B, which has reduced enzyme activity, had a higher survival rate than those with *GSTA1**A/*A and *GSTA1**A/*B.[250]

Platinum Compounds

Platinum-based drugs (cisplatin, carboplatin, and oxaliplatin) are widely used for the treatment of childhood solid tumors, including osteosarcoma, neuroblastoma, and hepatoblastoma (see Table 46-1).[251] Cisplatin (cis-diamminedichloroplatinum[II]) was first approved by the Food and Drug Administration in 1978, followed by carboplatin (cis-diammine[cyclobutane-1,1-dicarboxylate-O,O′] platinum[II]) in 1989 and oxaliplatin ([1*R*,2*R*]-cyclohexane-1,2-diamine[ethanedioato-O,O′] platinum[II]) in 2002. Although passive diffusion through the cellular lipid bilayer was hypothesized,[252-254] recent studies have shown the significant role of a variety of ion pumps and transporters.[255,256] The copper transporter protein copper transporter–1 (SLC31A1), which is involved in copper homeostasis, appears to be a major influx transporter of the platinum compounds.[257,258] ABCC2, ABCC4, copper-transporting P-type adenosine triphosphatases (ATP7B), MATE1, OCT1, and OCT2 are suggested to have a role in the cellular accumulation of platinum compounds.[259-263] GST catalyzes the conjugation of cisplatin with glutathione, which leads to its inactivation and excretion. Within cells, the platinum compounds are aquated and are then more reactive with the drug's cellular targets.[264-267] They bind to DNA and induce lesions that are recognized by multiple repair pathways, mainly the nucleotide excision repair system.[268-272] However, the mismatch repair system is also implicated in the recognition and repair of these lesions.[273,274] When the lesions cannot be repaired, apoptosis is induced through different signaling cascades.[275,276]

Previous studies using the lymphoblastoid cell lines have identified genetic variants associated with cisplatin-induced cytotoxicity (see Table 46-4).[277,278] *ERCC2* (excision repair cross-complementation group–2) is one of the genes involved in the nucleotide excision repair pathway; common variations in the *ERCC2* Lys751Gln G allele (TG or GG) were associated with poorer tumor response and shorter event-free survival than the TT allele in pediatric and young adult patients with osteosarcoma who were treated with cisplatin, suggesting that polymorphic variants in DNA repair genes could be useful predictors of response.[279]

Platinum compounds can cause adverse effects (e.g., ototoxicity and nephrotoxicity) in children, and cisplatin, carboplatin, and oxaliplatin have different toxicity profiles.[280] Cisplatin-induced hearing loss is usually bilateral and irreversible, affecting 41% to 61% of children treated, and several candidate genes may be associated with ototoxicity.[281] The *GSTM3**B allele was found to provide a protective effect against cisplatin-induced ototoxicity, compared with the *GSTM3**A allele.[282] GST genes were also associated with cisplatin-induced long-term hearing impairment in testicular cancer survivors; the genotype ^{105}Val/^{105}Val-*GSTP1* appeared to be protective in comparison with ^{105}Ile/^{105}Ile- or ^{105}Ile/^{105}Val-*GSTP1*.[283] The role of GST genes in other cisplatin-induced toxicities was confirmed by the discovery that *GSTM1* and *GSTT1* polymorphisms may affect cognitive impairment in children after treatment for medulloblastoma; patients with at least one null genotype were at greater risk than those without a null genotype.[284] Authors of another genotyping study of 1949 SNPs in 220 drug-metabolism genes in children identified genetic variants in *TPMT* (rs12201199, A allele) and catechol-O-methyltransferase *(COMT;* rs9332377, A allele) that were associated with cisplatin-induced hearing loss.[285] TPMT and COMT are methyltransferases dependent on the *S*-adenosylmethionine methyl donor substrate in the methionine pathway. The authors of this study proposed that higher levels of this substrate could provide a putative mechanism for cisplatin ototoxicity mediated by reduced TPMT and COMT activity. They suggested that decreased TPMT enzyme activity may also reduce the inactivation of cisplatin-purine compounds, thereby increasing cisplatin cross-linking efficiency and cisplatin toxicity, but no mechanistic data were provided. Megalin is a member of the low-density lipoprotein receptor family and is highly expressed in marginal cells of the *stria vascularis* of the inner ear, which accumulate high levels of platinum DNA adducts. The nonsynonymous SNP rs2075252 in *megalin* was found to be associated with cisplatin-induced ototoxicity.[286]

Irinotecan

Irinotecan, known as 7-ethyl-10-[4-(1-piperidino)-1-piperidino] carbonyloxycamptothecin or CPT-11, is a semisynthetic analogue of the natural alkaloid camptothecin (Fig. 46-11 and Table 46-1). It is a prodrug converted to its active metabolite, 7-ethyl-10-hydroxycamptothecin (SN-38), by carboxylesterases in the liver and gastrointestinal tract.[287,288] SN-38 is a potent topoisomerase I inhibitor and has shown promising activity against pediatric solid tumors alone or in combination with other chemotherapeutic agents.[289-291] Irinotecan is inactivated after oxidation by CYP3A4 to 7-ethyl-10-[4-N-(5-aminopentanoic acid)-1-piperidino] carbonyloxycamptothecin and 7-ethyl-10-(4-amino-1-piperidino) carbonyloxycamptothecin.[292,293] The majority of irinotecan and its metabolites are excreted in bile; bile excretion is enhanced by the formation of SN-38 glucuronide (SN-38G), catalyzed primarily by UGT1A1.[294]

The *UGT1A1*28* polymorphism reflects a change in the number of TA repeats in the TATA box of the *UGT1A1* promoter from the wild-type 6 repeats to the variant 7 repeats (Table 46-4).[295] Approximately 7% to 19% of the white population is homozygous (7/7) for the variant allele, as seen in Gilbert syndrome, which leads to reduced enzyme expression. Several studies in adults found that patients with the *UGT1A1*28* 7/7 genotype had lower SN-38G/SN-38 AUC ratios and greater toxicity after treatment with a high dosage of irinotecan (e.g., 350 mg/m^2, once a month) than did those with the 6/6 or 6/7 genotype.[296,297] Children with the *UGT1A1*28* 7/7 genotype who received low-dose irinotecan (15 to 75 mg/m^2) on a protracted schedule (5 days weekly for 2 consecutive weeks) tended to have higher SN-38 AUC values and lower SN-38G/SN-38 AUC ratios.[298] However, severe toxicity was not increased in these patients, suggesting that *UGT1A1* genotyping is not a useful predictor of severe toxicity for patients treated with this irinotecan dosage and schedule.

Temozolomide

Temozolomide is one of the imidazotetrazinone derivatives discovered in the 1980s and is used to treat CNS malignancies (see Table 46-1).[299] Temozolomide is a prodrug that undergoes spontaneous conversion to the reactive metabolite 5-(3-methyltriazen-1-yl-) imidazole-4-carboxamide (MTIC) under physiologic conditions.[300,301] MTIC is degraded to the methyldiazonium cation, which transfers its methyl group to DNA and to the final degradation product, 4-amino-5-imidazole carboxamide. The most common methylation site in DNA is the N^7 position of guanine, followed by the N^3 position of adenine and the O^6 position of guanine.[300,302] N^7-methylguanine and N^3-methyladenine, which constitute nearly 90% of the total methylation events, are efficiently repaired by the base excision repair pathway and have low cytotoxicity potential. O^6-methylguanine represents only 5% to 10% of methylation events, but these adducts trigger the DNA mismatch repair pathway and are highly cytotoxic. O^6-methylguanine methyltransferase (MGMT) is a cellular DNA repair protein that rapidly reverses alkylation (including methylation) at the O^6 position of guanine, thereby neutralizing cytotoxic effects.[303] MGMT can be silenced by abnormal methylation of CpG islands in its promoter region, which prevents DNA damage repair.[304,305] In several studies, adult patients with glioblastoma who had a methylated MGMT promoter had longer survival after temozolomide treatment than did patients without methylation.[306-308] Thus the methylation status of the MGMT gene promoter may provide a marker of temozolomide sensitivity. Results in the pediatric population are inconsistent, and more studies in larger cohorts are needed.[115,117,309]

Pharmacogenetics, Pharmacogenomics, and the Future

Many studies are underway to relate interindividual variability in pharmacokinetics to drug efficacy and toxicity and their implications for improving the therapeutic index of anticancer agents in children. Evaluation of the whole genome in a large series of patients will deepen our understanding of how pharmacogenetics and pharmacogenomics can be used to improve patient outcomes. This knowledge can be used to develop individualized therapy for patients. However, thus far the clinical application of pharmacogenomics research findings has been slow. The cost of genotyping will diminish over time and with advances in genomic technology, but the consistent interpretation of results and their efficient communication to the clinician are essential. Key components to successful clinical implementation of pharmacogenomics will include not only clinician understanding of pharmacogenomic test results but also availability of clinical prescription guidelines based on the test results,

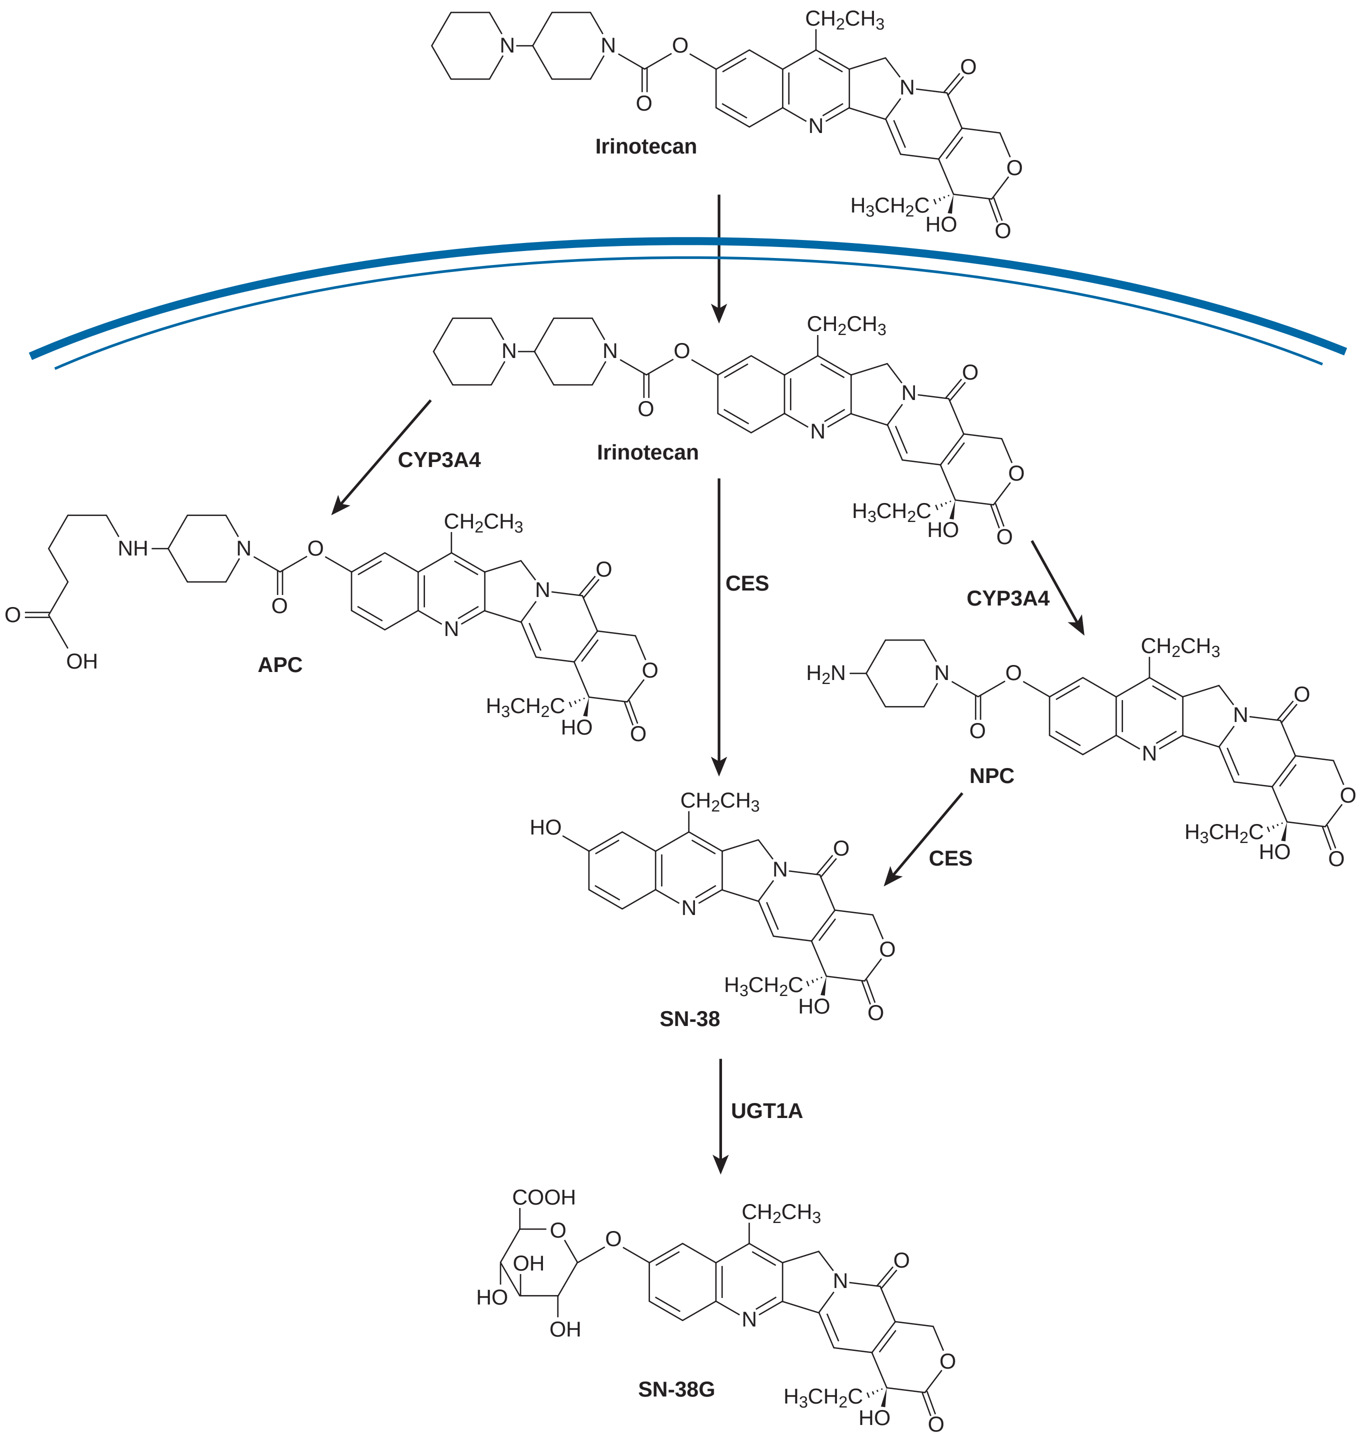

Figure 46-11 Metabolic pathways of irinotecan. Irinotecan is a prodrug converted to its active metabolite, 7-ethyl-10-hydroxycamptothecin (SN-38), by carboxylesterases *(CES)* in the liver and gastrointestinal tract. Irinotecan is inactivated after oxidation by CYP3A4 to 7-ethyl-10-94-N-[5-aminopentanoic acid]-1-piperidino) carbonyloxycamptothecin *(APC)* and 7-ethyl-10-(4-amino-1-piperidino) carbonyloxycamptothecin *(NPC)*. The majority of irinotecan and its metabolites are excreted in bile; bile excretion is enhanced by the formation of SN-38 glucuronide *(SN-38G)*, catalyzed primarily by uridine diphosphate *(UDP)*–glucuronosyltransferase 1A1 *(UGT1A1)*.

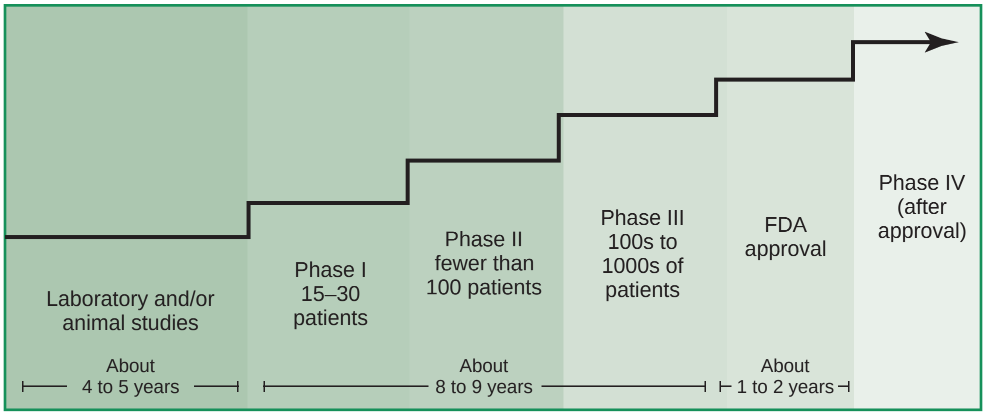
knowledge/evidence-based decision support systems, and appropriate sharing of this sensitive information with patients. Pharmacogenomics data cannot substitute for close clinical monitoring of patients, but they can be used to improve outcomes through informed treatment planning and anticipation of toxicities.

NEW DRUG DEVELOPMENT

The era of molecular-targeted therapy arrived with the approval of the *BCR-ABL1* inhibitor imatinib for treatment of chronic myeloid leukemia.[219] Numbers of new agents have been tested in clinical trials along with further



Laboratory and/or animal studies
Phase I 15–30 patients
Phase II fewer than 100 patients
Phase III 100s to 1000s of patients
FDA approval
Phase IV (after approval)
About 4 to 5 years
About 8 to 9 years
About 1 to 2 years

Figure 46-12 Clinical trials process. Clinical trials are conducted after preclinical development in laboratory and/or animal studies and encompass four phases. *FDA,* Food and Drug Administration.

understanding of molecular alterations and signal transduction pathways in pediatric cancer (see Table 46-1).

Whether for a single agent or for use in combination chemotherapy, determination of appropriate dosing through preclinical evaluation and clinical trials is crucial for appropriate use of new drugs. After preclinical development in cellular or animal models, clinical trials progress through four phases (Fig. 46-12).[310,311] The entire process can take more than 10 years. A phase I trial is performed to evaluate the safety of a new agent and the tolerable dosage. The study determines the maximum dose that can be given (maximum tolerated dose, MTD) without causing harmful side effects. Phase I trials enroll a small number of patients (15 to 30 patients) who have advanced cancers that cannot be treated effectively with standard regimens or for which no standard treatment exists. Although phase I trials do not focus on effectiveness, responses are recorded. The most important issue in pediatric phase I trials is selection of the appropriate investigational agent, because the number of pediatric participants is remarkably smaller than that of adult participants and therefore the number of agents that can be investigated is limited. Also, the new agent must be continuously available to progress through the stages of drug development, but it may be withdrawn by pharmaceutical firms if it lacks efficacy in adult trials.

A phase II trial evaluates the effectiveness of the new drug in patients with a specific type of cancer or a group of related cancers, typically by using the MTD determined in the phase I trial. Safety is also monitored. These studies usually enroll fewer than 100 patients but may include as many as 300, depending on the breadth of cancer diagnoses evaluated. The patients who participate in phase II trials may or may not have been treated previously with standard therapy for their type of cancer. Although efficacy in a specific population is the main question of phase II studies, these studies are almost never designed to compare the efficacy of an intervention with that of standard therapy. This comparison is done in phase III trials, which usually enroll large groups of patients (100 to several thousand). Participants are randomly assigned to groups that are typically stratified according to patient characteristics such as age, sex, and extent of disease to ensure that the groups have similar characteristics. This balance and patient number are important in confirming that the treatment is responsible for any significant differences between the two groups in responses or adverse effects. Randomization is usually accomplished by a computer-based algorithm, and trial participants or researchers cannot influence assignment to specific groups. Neither the participants nor their doctors may know what treatment the participants are receiving (double-blind study). Phase IV trials take place after Food and Drug Administration approval to evaluate the effectiveness and long-term safety of drugs in larger populations (several hundred to several thousand patients).

Preclinical Development

In general, preclinical data come from cytotoxic effects in vitro in various animal and human cancer cell lines and in vivo antitumor activity in mouse tumor models or in human tumors xenografted into immunodeficient mice.[312,313] In addition, toxicology studies are conducted in various species to determine toxicity end points, such as the lethal dose for 10% of the animals. These evaluations in vitro and in mouse models clearly have value in defining the target plasma drug concentrations, although direct extrapolation to humans is often difficult, because these models are oversimplified and can be influenced by species differences in metabolic transformation or any other form of drug elimination. Nonetheless, these studies may guide the choice of starting dosage and schedules of administration for phase I clinical trials. For example, if drug cytotoxic activity is shown to be S-phase–specific, prolonged exposure may be required, suggesting the use of a prolonged IV infusion if the agent has a relatively short terminal half-life. Preclinical data can also be valuable in defining the therapeutic window. Theoretically, it is possible to define a two-dimensional plasma concentration-versus-time window, the lower limit of which is the plasma concentration at which antitumor activity begins and whose upper limit is the plasma concentration at which unacceptable toxicity begins (see Fig. 46-1).[314] This approach is used to define the plasma concentration parameters for therapeutic drug monitoring and is widely used for cancer drugs and for numerous noncancer drugs, including antibiotics and antiretroviral agents.[315] In the United States, the Pediatric Preclinical Testing Program of the National Cancer Institute evaluates the therapeutic potential of new agents against molecular characteristics of pediatric cancers identified by the work of the St. Jude Children's Research Hospital and Washington University Pediatric Cancer Genome Project and others.[316]

Choice of Starting Dose for Clinical Studies

Historically, the starting dose of anticancer agents for early clinical trials has been selected empirically on the basis of toxicologic studies in rodents (mice and rats) and dogs; 10% of the murine lethal dose for 10% of the animals is often selected as the starting dose for safety studies in patients, because intolerable toxicity is unlikely at this dose.[312,313,317] Theoretical considerations and an extensive review of preclinical toxicologic studies support the appropriateness and safety of using toxicologic models based on mouse and rat data for anticancer drug development.[318,319] Importantly, however, much higher plasma concentrations can generally be achieved in animals than in humans, and this difference is not always explained by a difference in drug clearance. Therefore, in extrapolating the results of efficacy studies in tumor-bearing animals to clinical use, it is important to remember that these tumors have been exposed to drug levels that in most cases cannot be achieved in patients. This factor is particularly relevant when the relationship between plasma levels and antitumor effects is poorly understood.

Drug development for pediatric cancer has had to evolve while survival rates have improved, making fewer patients eligible for investigational drug studies.[311,313] Agents developed for use in adults may readily be investigated for potential pediatric use. However, new agents targeted to specific molecular abnormalities in adult cancers may have little value in treating pediatric cancers, which typically do not have the same underlying molecular abnormalities.

In a retrospective comparison of phase I studies performed between 1999 and 2004, the pediatric MTD was strongly correlated with the adult MTD. Adult data, such as MTD, pharmacokinetics, toxicity profile, and efficacy findings, are available for many candidate agents. Dose-finding pediatric phase I studies often start at approximately 80% of the adult MTD,[313] even though the MTD in children is often higher when adjusted to BSA. Pediatric formulations (e.g., liquid formulation or crushed form of tablets) are often necessary for younger children who cannot swallow capsules or tablets. However, pharmaceutical companies have little financial incentive to invest in the development of pediatric formulations, which have a very small market. It should also be recognized that the "starting dosage" is typically a dosage that has been tolerated by essentially everyone and thus will be lower than the MTD for patients with rapid drug clearance, and perhaps intolerable for a small subset of patient with very slow drug clearance (possibly because of an inherited defect in drug metabolism, as exemplified by TPMT and mercaptopurine, in which 1 in ~400 children can tolerate only 10% of the standard dosage).

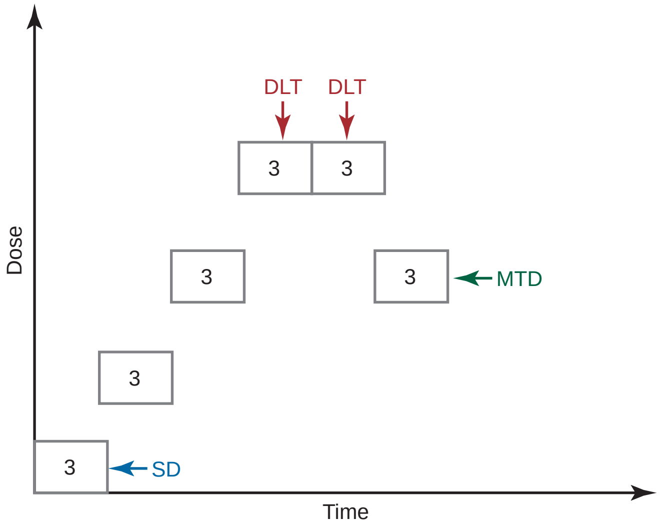


Figure 46-13 Graphic depiction of dose escalation methods using the traditional 3+3 design in phase I cancer clinical trials. Each box represents a cohort consisting of the indicated number of patients treated at a given dose level. After three patients have undergone treatment without experiencing dose-limiting toxicity *(DLT)*, the dose is escalated for the next set of three patients. *MTD*, Maximum tolerated dose; *SD*, starting dose.

Dose Escalation Schemes

Most phase I oncology trials use rule-based designs, which include the traditional 3+3 design or its variations.[312] This model implements any prior assumptions of the dose-toxicity curve. Doses are escalated or de-escalated by using the "up-and-down" methods created by Dixon and Mood in 1948.[320] In the 3+3 model, a minimum of three participants are evaluated at each dose level (Fig. 46-13). If none of the three experiences a dose-limiting toxicity (DLT), an additional three participants are enrolled at the next higher dose level. If one of the three experiences a DLT, an additional three participants are evaluated at the same dose level. Dose escalation continues in this manner until at least two participants in a cohort of three or six experience DLT (i.e., >33% of participants have a DLT at this dose level). Because the MTD is exceeded at this level, an additional three participants (as high as a total of six) are treated at the next lower dose level, which is defined as the MTD if no more than one of six participants (0% to 17%) experience DLT.

Dose escalation is usually based on the modified Fibonacci sequence, in which steps escalate in decreasing increments (e.g., 100%, 67%, 50%, 40%, and 30% to 35% of preceding doses). Because good correlation between adult and pediatric MTDs has been shown, little value exists in testing more than four dose levels or testing dose levels greater than 1.6 times the adult MTD.[321] Limiting pediatric phase I trials to a maximum of four dose levels increasing in 30% increments (e.g., 0.7, 1.0, 1.3, and 1.6 times the adult MTD) would significantly shorten the time required for study completion and can expect therapeutic activity, although it is not the major purpose. Historically, children participating in phase I studies have been treated with therapeutic intent, although legal guardians and/or patients should be fully informed that the focus of a phase I study is safety rather than efficacy.[322]

Alternative rules other than the 3+3 design have been proposed to shorten the study time line.[312] For example, accrual is suspended after enrollment of the third patient in each cohort. Further, when one of the three patients in a cohort cannot be evaluated for toxicity (usually because of disease progression), the cohort would not be completed until one additional patient completes the evaluation. The "rolling 6" design[323] has been proposed to shorten the time frame by allowing concurrent enrollment of two to six patients at a dose level. The decision about the dose level at which to enroll upcoming patients is based on the number of the patients currently enrolled and evaluable, the number of patients experiencing DLT, and the number of patients still at risk of DLT. For example, when three participants are enrolled at a dose level, if toxicity data are available for all three and no DLTs have been observed, the fourth participant is enrolled at the next higher dose level. If toxicity data are not yet available for all three participants but no DLT has been observed, or if one patient has experienced DLT, the new participant is enrolled at the same dose level. If two or more of the three participants have experienced DLT, the dose level is de-escalated. This process is repeated for the fifth and sixth participants. Accrual is suspended only when a cohort of six is filled. A discrete-event simulation study showed that the rolling 6 model significantly shortened the duration of pediatric phase I trials without increasing the risk of toxicity; this strategy has been incorporated into pediatric phase I studies.[324]

Parameter Estimates

The pharmacokinetic parameters of the investigational agent, including peak concentration, drug clearance, half-life, Vd, AUC, and metabolic profile, should be defined at different dose levels to be used clinically.[312,313] Because the effect of a therapeutic agent in the body is generally a function of its concentration at the (molecular) site of action, a description of the spatial-temporal behavior of the drug in the body is helpful, if not essential, for understanding and predicting normal tissue toxicity and optimizing tumor response.[312,313] Measures of drug exposure (e.g., AUC) are clearly more informative than the absolute dose. Ideally, drug exposure should be measured at the molecular locus of action or at least at the tissue or tumor level, but with the exception of leukemia, drug concentrations are usually measured only in plasma, which is the only readily accessible surrogate. The detection of metabolites and definition of their pharmacokinetic behavior and pharmacologic activity are also extremely important, particularly in the case of agents that require metabolic activation, such as cyclophosphamide and irinotecan.

Data from early clinical studies can be used to define the therapeutic window of the agent and design more rational schedules of administration and combination therapies; it may also provide clues about potential cumulative toxicity or organ-specific toxicity. The measured parameters can be compared with the observed clinical outcome, particularly in terms of toxicity, to help define pharmacokinetic-pharmacodynamic relationships that may be of use in further clinical testing of the agent. In addition, dose-effect relationships, at least in terms of toxicity, can best be assessed at this early stage of clinical development, when a wide range of doses is being administered to patients.

After a dose is selected, the same dose is usually maintained throughout treatment unless serious toxicity occurs, in which case the dose is empirically decreased during subsequent treatment courses. In contrast, the dose of chemotherapy is rarely increased in the absence of toxicity, despite the possibility of undertreatment. Although wide interpatient variability has been demonstrated in all aspects of anticancer drug pharmacokinetics, several studies have observed reasonably predictive relationships between a measure of drug exposure and toxicity or antitumor efficacy in pediatric patients (Table 46-5). These findings would add to the argument to

TABLE 46-5 Pharmacokinetic-Pharmacodynamic Relationships of Chemotherapeutic Agents

Drug	Toxicity/Efficacy (Disease)	Pharmacokinetic Parameter
Busulfan	Hepatotoxicity	AUC
Carboplatin	Thrombocytopenia	AUC
Cisplatin	Nephrotoxicity Neurotoxicity	C_{max} (unbound drug) C_{max} (unbound drug)
Cyclophosphamide	Cardiotoxicity	AUC
Docetaxel	Neutropenia	AUC
Doxorubicin	AML Leukocytopenia Thrombocytopenia	$C_{3\ hr}$ AUC Doxorubicinol AUC
5-Fluorouracil	Mucositis Leukocytopenia	AUC >30 µg × h/mL AUC and C_{ss}
Irinotecan	Neutropenia Diarrhea	AUC Biliary index
6-Mercaptopurine	ALL	AUC; RBC 6-TGN levels
Methotrexate	Mucositis, myelosuppression	$C_{48\ hr}$ >0.9 µM
Paclitaxel	Neutropenia	Time above 0.05 µM
Teniposide	Lymphoma, leukemia	C_{ss} and CL
Topotecan	Myelosuppression	Lactone AUC
Vinblastine	Neutropenia	C_{ss}
Vincristine	Neurotoxicity	AUC

ALL, Acute lymphoblastic leukemia; *AML,* acute myeloid leukemia; *AUC,* area under the plasma concentration vs. time curve; $C_{3\text{-}hr}$, plasma concentration 3 h after intravenous bolus administration; $C_{48\ hr}$, plasma concentration at 48 h; C_{max}, peak plasma concentration; C_{ss}, plasma concentration at steady state; *CL,* total plasma clearance; *RBC,* red blood cell; *6-TGN,* 6-thioguanine nucleotide (intracellular active metabolite of 6-mercaptopurine).

increase the dose in cases of limited toxicity, although this question remains unresolved.

Various mathematical models have been used to analyze the relation between drug concentration in biologic fluids (e.g., plasma) and the pharmacologic effects of anticancer agents. One such model is the modified Hill equation or the E_{max} model—that is, the drug concentration producing the maximum effect. The Hill equation reflects the sigmoidal relationship of pharmacologic response to AUC, steady state exposure, and threshold concentration, respectively; the response is usually measured as hematologic toxicity, expressed as a percentage. A number of commonly used anticancer drugs, including carboplatin, doxorubicin, etoposide, teniposide, mercaptopurine, 5-fluorouracil, paclitaxel, and vinblastine, have demonstrated this type of relationship.[325] When nonhematologic toxicities are dose limiting, they can be more difficult to model because of the subjective nature of grading them, in contrast to hematologic toxicity, which is a more quantitative continuous variable. However, efforts to model these adverse effects have yielded useful correlations between nephrotoxicity and cisplatin AUC and between gastrointestinal toxicity and glucuronidation rates of the irinotecan metabolite, SN-38.[326]

Clinical trials in childhood ALL that revealed a relation between drug clearance or drug exposure (AUC or steady state plasma concentration) and treatment efficacy (event-free survival) also have been conducted[327,328]; therefore treatment outcome may be improved by randomized clinical trials that adjust doses on the basis of drug clearance.[5]

STRATEGIES TO IMPROVE THE THERAPEUTIC INDEX

Dosage Based on Body Surface Area

The traditional method of individualizing anticancer drug dosage in children is by using body surface area (BSA) (Table 46-6).[329,330] BSA has become the standard variable for determining the dose of anticancer agents in pediatric patients for several reasons. First, an established correlation exists between BSA and some relevant individual patient characteristics, such as GFR, blood volume, and basal metabolic rate.[331] Second, the starting dose of agents in phase I studies is based on data derived from animal models, in which the drug dose is calculated on the basis of weight (mg/kg) or BSA (mg/m²). Third, in the 1950s, when attempts were first made to define a more accurate method for administration of cytotoxic drugs to children, several studies suggested that BSA be used in dose calculation. In 1958, Pinkel[332] reported a retrospective analysis that used a BSA-based formula for adults and children and Meeh's formula for animals to determine the pediatric and adult doses of five cytotoxic drugs (mercaptopurine, methotrexate, mechlorethamine, triethylene thiophosphoramide, and actinomycin). When the conventional doses were calculated according to unit surface area, similar values were obtained for all agents tested in children and adults except for mercaptopurine; therefore, the author recommended that doses of cytotoxic agents be normalized by using BSA.

TABLE 46-6 Strategies to Improve Therapeutic Index of Anticancer Drugs in Children

Dose Adjustment Method	**Example**
Based on Patient Characteristics	
Body surface area*	All drugs
Based on Pharmacokinetic-Pharmacodynamic Principles	
Therapeutic drug monitoring	Methotrexate, 5-fluorouracil, busulfan, etoposide, cisplatin
Feedback-controlled dosing	Methotrexate
Circadian rhythm–based dosing	6-Mercaptopurine, busulfan, carboplatin, docetaxel, 5-fluorouracil, oxaliplatin
Biomodulation	
Pharmacokinetic modulation	CYP3A4 inhibitor (erythromycin, quinidine, ketoconazole, cyclosporin A) ABCB1 inhibitor (cyclosporin A)
Pharmacodynamic modulation	Leucovorin for methotrexate and 5-fluorouracil Amifostine for cisplatin Dexrazoxane for anthracycline Cefixime for irinotecan
Drug scheduling	Etoposide, methotrexate, dexamethasone
Drug administration sequence	Methotrexate–5-fluorouracil Lestaurtinib–chemotherapeutic agents in acute lymphoblastic leukemia Deoxyadenosine analogues (fludarabine, cladribine, clofarabine)–cytarabine
Based on Pharmacogenetic Principles	
Pharmacogenetics-based dosing	6-Mercaptopurine (*TPMT*)

ABC, Adenosine triphosphate–binding cassette transporter; *CYP,* cytochrome P-450 enzyme; *TPMT,* thiopurine methyltransferase.
*Weight (mg/kg) is used in children who weigh less than 10 kg.

BSA is commonly estimated by using a formula derived primarily to determine basal metabolism from weight and height alone; more recently, the original formula has been confirmed as surprisingly accurate, considering the small sample size used in deriving it.[330] The formulas by Mosteller

$$BSA = \sqrt{\frac{W \times H}{3600}} = 0.016667 \times W^{0.5} \times H^{0.5}$$

and Du Bois

$$(\mathrm{BSA} = 4.688 \cdot \mathrm{W}^{(0.8168 - 0.0154 \cdot \log \mathrm{W})})$$

are most commonly used.[333] Because of the difficulty of measuring height in infants and their physiologic differences from older children (e.g., a higher proportion of body water and a lower proportion of body fat, immature enzyme systems, and lower renal clearance rates), the majority of pediatric protocols apply a 10-kg cutoff for surface area–based dosing.[333] Below this weight, the dosing of chemotherapeutic drugs is specified on a mg/kg basis, usually based on the assumptions that an individual with BSA of 1-m^2 weighs 30 kg and that there is a linear relationship between weight and BSA. This method may result in significantly lower calculated doses for children whose body weight is less than 10 kg. This lower dose may avert excessive toxicity in infants and younger children, who have immature hepatic and renal function. However, some patients may receive subtherapeutic dosing, and a significant step-up in dosage can occur as children cross the 10 kg boundary by moving from mg/kg to mg/m^2 dosing during their treatment.

The usefulness of normalizing anticancer drug dose to BSA in adults has recently been questioned, because BSA does not vary as widely in adults as in children and is not related to the clearance of most anticancer drugs in adults.[334] BSA is considered more important for drug dose calculation in pediatric patients, whose BSA values vary over a greater range.[335]

Pathophysiologic Status

Most pharmacologic studies of anticancer agents have shown important interindividual and intraindividual variability in pharmacokinetic behavior. In some cases, this variation is caused by cancer-induced changes in physiologic status or dysfunction of specific organs involved in drug elimination (Table 46-7). For example, if urinary excretion is an important elimination route for a given drug, any decrement in renal function could decrease drug clearance and result in drug accumulation and toxicity. It would therefore be logical to reduce the drug dose relative to the degree of impaired renal function to maintain plasma concentration within a targeted therapeutic window, as has been well documented for bleomycin, carboplatin, cisplatin, cyclophosphamide, etoposide, methotrexate, and topotecan.[336] The best known example of this a priori dose adjustment of an anticancer agent is carboplatin, which is excreted renally, almost entirely by glomerular filtration. Various strategies have been developed to estimate carboplatin dose on the basis of renal function of patients, either by using creatinine clearance[337] or radioisotopically measured GFR.[338] Use of these methods has substantially reduced pharmacokinetic variability, such that carboplatin is one of the few drugs routinely administered to achieve a targeted exposure rather than on a mg/m^2 or mg/kg basis.

TABLE 46-7 Characteristics That Affect the Pharmacokinetics of Chemotherapeutic Agents in Children

Parameter	Anticancer Drug
Renal function	Bleomycin, carboplatin, cisplatin, cyclophosphamide, etoposide, methotrexate, topotecan
Hepatic function	Anthracyclines, vinblastine, vincristine
Serum albumin	Etoposide, dexamethasone
Third spaces	Methotrexate

Although a decline in renal clearance of drugs can be predicted when glomerular filtration is impaired, it is less easy to predict the effect of impaired liver function on drug clearance. The main problem is that hepatic enzymes are typically poor indicators of metabolizing activity or anticancer drug pharmacokinetics. A proposed alternative dynamic measure of liver function is based on the sum of serum bilirubin, alkaline phosphatase, and either alanine aminotransferase or aspartate aminotransferase values (each scored according to the World Health Organization grading system) to provide a hepatic dysfunction score.[339] Guidelines based on carefully conducted pharmacokinetic studies in patients with normal and impaired hepatic function have been proposed for adjustment of the doses of several agents, including anthracyclines (doxorubicin and daunorubicin), etoposide, and vinca alkaloids (vinblastine and vincristine), for patients with liver dysfunction.[340]

The binding of drugs to plasma proteins, particularly when drugs are highly bound, may also have significant clinical implications for therapeutic outcome.[341] Although protein binding is a major determinant of drug action, it is clearly only one of a myriad of factors that influence drug disposition. The extent of protein binding is a function of drug and protein concentrations, the affinity constants for the drug-protein interaction, and the number of protein-binding sites per class of binding site. Because only unbound (or free) drug in plasma is available for diffusion from the vascular compartment to the tumor interstitium, the therapeutic response will be related to free drug concentration rather than total drug concentration. Several clinical factors, including liver and renal disease, can significantly decrease the extent of plasma binding and may increase free drug concentration and the risk of unexpected toxicity, despite unaltered total (free plus bound forms) plasma drug concentration. High systemic exposure to asparaginase induces hypoalbuminemia and is associated with lower apparent clearance of dexamethasone in patients with ALL.[342] Hepatic synthesis of proteins involved in dexamethasone clearance, rather than decreased plasma protein binding, is thought to be implicated in such cases. Third-space fluid collection, such as pleural effusion and ascites, alters the pharmacokinetics of chemotherapeutic agents (e.g., methotrexate), and dose modification and strict monitoring are required.

Adjustment of the dosage a posteriori on the basis of a patient's tolerance is also widely practiced, although it may result in dose reduction, which can compromise dose intensity and lead to treatment failure. Clearly, the seriousness of the first adverse effect is the major determinant of whether it can be used as an end point. Examples of this type of dose adjustment are the platelet nadir-directed individualized approach to carboplatin dosage[343] and leukopenia-targeted dosing of methotrexate and mercaptopurine in children with ALL.[344] However, this approach can be untenable when, as often occurs, treatment consists of multiple anticancer agents with overlapping toxicities (especially hematologic toxicity).

Dose Adaptation Using Pharmacokinetic-Pharmacodynamic-Pharmacogenetic Principles

Therapeutic Drug Monitoring

Prolonged infusion schedules offer a very convenient setting for anticancer drug dose adaptation in individual patients. When steady state concentration is achieved, it is possible to modify the infusion rate for the remainder of the treatment course if a relationship is known between this steady state concentration and a desired pharmacodynamic end point (see Table 46-6). This method has been successfully used to adapt the dose during continuous infusions of methotrexate, 5-fluorouracil, busulfan, and etoposide, and for repeated oral administration of etoposide or repeated IV administration of cisplatin.[340] Methotrexate plasma concentration is routinely monitored after administration of high-dose methotrexate to identify patients at high risk of toxicity and to adjust leucovorin rescue and hydration in patients with delayed excretion. In some cases, ongoing methotrexate infusion can be slowed or discontinued if the concentration is considered to be critically high. Such monitoring has significantly reduced the incidence of serious toxicity (including toxic death) and has in fact improved outcome by eliminating unacceptably low systemic exposure.[5]

Feedback-Controlled Dosing

It remains to be seen how information about variability can eventually be used to devise an optimal dosage regimen of a drug for the treatment of a given disease in an individual patient. Obviously, the desired objective would be most efficiently achieved if the individual's dosage requirements could be calculated before the drug is administered. Although this ideal cannot be completely met in clinical practice, some success may be achieved by adopting feedback-controlled dosing, as in the case of methotrexate (see Table 46-6).[5,345] In adaptive dosage with feedback control, population-based predictive models are initially used but allow the possibility of dosage alteration based on feedback revision. In this approach, patients are first treated with the standard dose, and then during treatment pharmacokinetic information is estimated by a limited-sampling strategy, and compared with that predicted from the population model with which dosage was initiated. More patient-specific pharmacokinetic parameters are calculated on the basis of this comparison, and dosage is adjusted accordingly to maintain the target exposure that produces the desired pharmacodynamic effect for subsequent courses. It has been proposed that, despite its mathematical complexity, this approach may be the only way to achieve the desired precise exposure of an anticancer agent. The use of population pharmacokinetic models is increasingly studied in adults in an attempt to accommodate as much pharmacokinetic variability as possible in terms of measurable characteristics, and mathematical equations based on BSA, gender, and protein levels are provided, for example, to predict drug clearance with an acceptable degree of precision.

Circadian Rhythm–Based Dosing

Administration at certain times of the day may improve the therapeutic index of several anticancer drugs (see Table 46-6).[346,347] For example, significant improvement in survival has been demonstrated for children with ALL who received 6-mercaptopurine in the evening compared with the morning.[348] Chronotherapy schedules based on this concept showed improved tolerability in several clinical trials using other anticancer drugs, including busulfan, carboplatin, docetaxel, 5-fluorouracil, and oxaliplatin.[349-351]

Although the precise mechanisms are still unknown, such findings have led to the assumption that tolerability rhythms are coupled with the rest-activity cycle in patients with cancer. For example, one of the major limiting factors for 6-mercaptopurine is bone marrow toxicity. Normal bone-marrow cells are thought to have their nadir of DNA synthesis activity at night.[352] Thus administration of 6-mercaptopurine in the evening could provide normal cells an advantage over leukemic cells, which have minimal and variable diurnal changes in DNA synthesis. It remains unclear whether the potential benefits will justify the major inconvenience of drug administration in the middle of the night.

Pharmacogenetics-Based Dosing

The *TPMT* genetic polymorphism probably best illustrates the potential impact of pharmacogenetics on pediatric oncology (Figs. 46-6 and 46-7; see also Table 46-6).[87] TPMT plays an important role in inactivation of thiopurines (6-mercaptopurine, 6-thioguanine, and azathioprine) by catalyzing the transfer of the methyl group from *S*-adenosyl methionine to the sulfur atoms of thiopurines. TPMT-deficient patients accumulate excessive concentrations of thioguanine nucleotides after conventional doses of thiopurines, leading to severe and potentially fatal hematologic toxicity.[353,354] Heterozygous patients have an intermediate risk of toxicity and typically require only a modest dose reduction (as much as 50%), whereas patients who have inherited two nonfunctional alleles require treatment with only 5% to 10% of the standard dose to avoid toxicity without compromising efficacy.[92,355,356] Pretreatment knowledge of a patient's TPMT status is now used for dose optimization to reduce the likelihood of toxicity.[356] *TPMT* genotyping (e.g., use of restriction fragment length polymorphism or high-throughput DNA arrays such as the Affymetrix DMET chip [Affymetrix, Santa Clara, Calif.]) is highly efficient in identifying patients at risk of thiopurine-related toxicity. TPMT enzymatic activity in erythrocytes can also be directly measured by radiochemical assay, but heterologous red blood cell transfusions within the past ~30 to 60 days can cause spurious results.

Mercaptopurine, thioguanine, and their metabolites (e.g., thioguanine nucleotides) can be quantified by reverse-phase high-performance liquid chromatography assay.[357] A significant inverse relationship between TGN and TPMT activity in erythrocytes has been observed in several studies, and acute hematologic toxicity (e.g., neutropenia) has been clearly related to erythrocyte TGN concentration; unacceptable toxicity is reported when doses of 50 to 75 mg/m^2 per day are given to children with *TPMT* deficiency.[353,358] When thiopurines are administered according to genotype, comparable cellular thioguanine nucleotide concentrations are achieved; therefore all patients, regardless of *TPMT* phenotypes, can be treated without adverse effects and without compromising efficacy. It is unclear whether adjustment of thiopurine doses on the basis of TGN levels improves treatment efficacy, but TGN measurement is helpful for detecting noncompliance and explaining hematopoietic toxicity.[358,359]

Intentional Biomodulation

Pharmacokinetic Alterations. Intestinal metabolic systems and drug efflux pumps located in the intestinal mucosa are another limitation of the bioavailability of orally administered drugs.[360] Several enzymes located in enterocytes, such as CYP3A4, are involved in the presystemic metabolism of many cytotoxic agents, including cyclophosphamide and etoposide, thereby limiting the oral absorption of these drugs.[361] The bioavailability of these drugs might be substantially enhanced by pharmacologic modulation of enteric CYP3A4 activity (see Table 46-6). Several investigators confirmed that coadministration of specific inhibitors of CYP3A4 activity, such as erythromycin, quinidine, ketoconazole, and cyclosporin A, increase the oral bioavailability of various anticancer agents such as etoposide while also diminishing variability in absorption.[362] Similarly, ABCB1, which is abundantly present in the gastrointestinal tract, has been shown to limit intestinal absorption of numerous (anticancer) agents.[363] Combined inhibition of intestinal ABCB1 and CYP3A4 by cyclosporin A was shown to substantially increase systemic exposure to oral paclitaxel in adult patients with cancer,[364] suggesting that simultaneous modulation of transporter and enzyme could be considered when anticancer agents that have poor bioavailability are given orally.

Pharmacodynamic Alterations. The coadministration of specific agents with anticancer drugs to increase the therapeutic index has made a substantial impact in certain diseases (see Table 46-6). One of the most widely used biomodulating agents is leucovorin, a reduced folate used in combination with both methotrexate and 5-fluorouracil. This agent has been shown to decrease methotrexate-induced toxicity in various normal tissues and to enhance 5-fluorouracil–mediated cytotoxicity to tumor cells by inhibition of thymidylate synthase, thereby allowing escalation of the anticancer drug dose without affecting its disposition profile.[365] Other examples of agents that interfere with anticancer drug pharmacodynamics to reduce toxicity include (1) the use of amifostine to reduce cisplatin-associated myelosuppression, nephrotoxicity, and neurotoxicity,[366] (2) dexrazoxane to decrease anthracycline-induced cardiotoxicity,[367] and (3) coadministration of cefixime to ameliorate irinotecan-induced diarrhea.[290]

Pharmacodynamic biomodulation with ABCB1-blocking agents has also been extensively studied in adults in an attempt to improve the therapeutic index of anticancer agents.[368] This multidrug-resistant drug-efflux transporter encoded by the *ABCB1* gene is abundant in various types of human cancer. Studies performed during the past several years have shown that intrinsic and acquired expression of ABCB1 may play a role in clinical drug resistance in specific hematologic malignancies. Consequently, in clinical trials performed worldwide, ABCB1 blockers such as verapamil and cyclosporin A have been administered with anticancer drugs with the intent of attenuating carrier-mediated tumor-cell drug resistance. Unfortunately, decreased systemic clearance of the anticancer drugs became a serious problem in these trials and necessitated substantial dose reductions, thereby precluding the potential benefits of increased antitumor activity.[368] In most cases, pharmacokinetic interference appears to be the result of competition for enzymes (mainly CYP3A4) involved in drug metabolism.[369]

Although this modulation can be beneficial in pediatric cancer treatment, prospective pharmacokinetic and pharmacodynamic studies must be conducted to determine at which level (i.e., kinetics or dynamics) the interaction takes place and whether biomodulation ultimately improves the therapeutic index of anticancer agents.

Drug Scheduling and Sequence of Administration

The antitumor activity of certain chemotherapeutic agents is highly schedule dependent (see Table 46-6). For these drugs, the antitumor response or toxicity profile of a dose fractionated over several days can differ from those of the same dose given over a shorter period. For example, markedly greater efficacy in adult patients with small-cell lung cancer was documented when an identical total dose of etoposide was administered on a 5-day divided-dose schedule rather than as a 24-hour infusion.[370] Pharmacokinetic analysis showed that both schedules produced very similar overall systemic drug exposure (as measured by AUC) but that the divided-dose schedule produced twice the duration of exposure to an etoposide plasma concentration >1µg/mL. This observation was consistent with preclinical data, and the authors speculated that the duration of exposure to this threshold concentration was important in achieving clinical efficacy. This finding has led to the use of prolonged oral administration of etoposide to treat pediatric leukemia and solid tumors.[371,372] Similar schedule dependency has been demonstrated for a number of other anticancer agents. In children with ALL, 24-hour infusion of high-dose methotrexate (1 g/m^2) produced significantly greater accumulation of MTXPG$_{1-7}$ in leukemia cells than did 4-hour infusion.[373] The 24-hour infusion increased the duration of methotrexate exposure greater than 1 µmol/L by a factor of 2.5, producing greater inhibition of de novo purine synthesis in bone-marrow ALL cells and greater reduction of circulating leukemia cells. Furthermore, alternate-week (10 mg/m^2 per day on days 0 to 6 and 14 to 20) rather than continuous (10 mg/m^2 per day on days 0 to 20) administration of dexamethasone in childhood ALL significantly reduced osteonecrosis despite delivering a higher cumulative dose.[142]

Combinations of anticancer drugs can also exhibit schedule-dependent toxicity or antitumor activity,

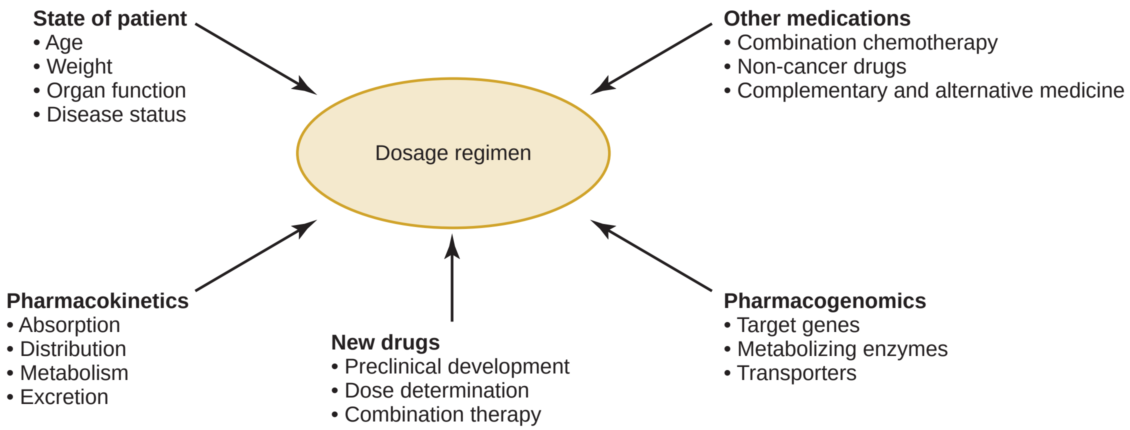

Figure 46-14 Determinants of the dosage regimen for an anticancer drug.

reflecting either pharmacokinetic or pharmacodynamic modulation. For example, the sequence of administration of 5-fluorouracil and methotrexate seems to determine the tumor cytotoxicity of this combination. In vitro, if methotrexate precedes 5-fluorouracil by at least 1 hour, synergistic results are obtained,[374] which may be due to increased activation of 5-fluorouracil to its nucleotide form. The opposite sequence of administration leads to drug antagonism due to blockage of the thymidylate synthase pathway by 5-fluorouracil. This blockage preserves the intracellular folates in their active tetrahydrofolate form, which diminishes the inhibition of dihydrofolate reductase by methotrexate. Similarly, a sequence-dependent interaction was observed in the treatment of *MLL*–rearranged ALL cells with the fms-related tyrosine kinase–3 (FLT3) inhibitor lestaurtinib and six chemotherapeutic agents (dexamethasone, vincristine, L-asparaginase, daunorubicin, cytarabine, and etoposide).[375] When chemotherapy was given before lestaurtinib, the combination was markedly synergistic, whereas the opposite sequence was antagonistic. This sequence dependence was caused by cell cycle suppression via FLT3 inhibition. Deoxyadenosine analogues such as fludarabine, cladribine, and clofarabine have been used in patients with leukemia.[376-378] They inhibit ribonucleotide reductase and decrease de novo synthesis of deoxynucleotide, lessening the feedback inhibition of deoxycytidine kinase. When combined with cytarabine in patients with AML, deoxyadenosine analogues are given first to increase the intracellular ara-CTP accumulation in leukemia cells.

In vitro and in vivo studies and phase I and II trials of combination chemotherapy typically reveal relevant pharmacokinetic and pharmacodynamic interactions and define drug doses and sequences of administration that can be safely administered.

CONCLUSION AND PERSPECTIVES

Substantial progress has been made in the optimization of cancer chemotherapy in recent years with the contributions of pharmacokinetics, pharmacodynamics, and pharmacogenetics and our increasing knowledge about physiologic changes associated with growth and development, the role of disease status, and drug-drug interactions (Fig. 46-14). Pharmacogenomics studies now include the application of next-generation sequencing technologies to cover all genetic variants,[284,285] and the inherited nature of differences in drug disposition and pharmacodynamic effects is being elucidated to provide a stronger scientific basis for optimization of drug therapy on the basis of an individual patient's genome.[30,286] The development of technologies such as cancer genome analysis, high-throughput drug screening, and combinatorial chemistry is likely to exponentially increase the number of drug targets and candidate compounds, and a deeper understanding of each compound's pharmacologic properties is expected to emerge during the exploratory stages of drug development.[287] In addition, the enormous quantity of patient-oriented information will require the use of models and computer simulation to guide clinical decisions for individualized therapy (i.e., systems biology).[288,289] In the next several years we should see the growth of targeted anticancer chemotherapy designed to exploit genetic abnormalities in individual tumors, with the reduction of toxicity and the enhancement of efficacy through judicious analysis of constitutional and genomic factors that modulate the pharmacokinetics (e.g., absorption, distribution, metabolism, and excretion) and pharmacodynamics (e.g., sensitivity and resistance) of chemotherapeutic agents.

   This report describes the clinical characteristics of osteonecrosis and shows that its incidence is influenced by the administration schedule of dexamethasone.

146. Pieters R, Hunger SP, Boos J, et al: L-asparaginase treatment in acute lymphoblastic leukemia: a focus on Erwinia asparaginase. *Cancer* 117:238–249, 2011.

   This article provides an overview of asparaginase in the treatment of acute lymphoblastic leukemia.

162. Kawedia JD, Liu C, Pei D, et al: Dexamethasone exposure and asparaginase antibodies affect relapse risk in acute lymphoblastic leukemia. *Blood* 119:1658–1664, 2012.

   This report describes the influence of antiasparaginase antibodies on acute lymphoblastic leukemia therapy, showing that patients with antibodies have higher systemic dexamethasone clearance rates. Lower exposure to both drugs was associated with greater risk of relapse.

199. Visscher H, Ross CJ, Rassekh SR, et al: Pharmacogenomic prediction of anthracycline-induced cardiotoxicity in children. *J Clin Oncol* 30:1422–1428, 2012.

   References 198 and 199 report the identification of genetic variants associated with anthracycline cardiotoxicity in children with cancer.

212. Lamba JK: Genetic factors influencing cytarabine therapy. *Pharmacogenomics* 10:1657–1674, 2009.

   This article summarizes the metabolism of cytarabine and the pharmacogenomics of cytarabine therapy.

219. Druker BJ, Talpaz M, Resta DJ, et al: Efficacy and safety of a specific inhibitor of the BCR-ABL tyrosine kinase in chronic myeloid leukemia. *N Engl J Med* 344:1031–1037, 2001.

   This study was the first to show significant activity of imatinib against chronic myeloid leukemia.

222. Biondi A, Schrappe M, De Lorenzo P, et al: Imatinib after induction for treatment of children and adolescents with Philadelphia-chromosome-positive acute lymphoblastic leukaemia (EsPhALL):

a randomised, open-label, intergroup study. *Lancet Oncol* 13:936–945, 2012.

The authors of references 221 and 222 assessed the safety and efficacy of imatinib for pediatric patients with Philadelphia-chromosome–positive acute lymphoblastic leukemia.

311. Balis FM, Fox E, Widemann BC, et al: Clinical drug development for childhood cancers. *Clin Pharmacol Ther* 85:127–129, 2009.

This article describes current issues in clinical drug development for childhood cancers.

312. Le Tourneau C, Lee JJ, Siu LL: Dose escalation methods in phase I cancer clinical trials. *J Natl Cancer Inst* 101:708–720, 2009.

The authors of this article review dose escalation methods for phase I trials, including the rule-based and model-based methods developed to evaluate new anticancer agents.

316. Downing JR, Wilson RK, Zhang J, et al: The Pediatric Cancer Genome Project. *Nat Genet* 44:619–622, 2012.

This perspective article describes the rationale for the Pediatric Cancer Genome Project, presents some of its early results, and discusses the major lessons learned and how they will affect the application of genomic sequencing in the clinic.

356. Relling MV, Gardner EE, Sandborn WJ, et al: Clinical Pharmacogenetics Implementation Consortium guidelines for thiopurine methyltransferase genotype and thiopurine dosing: 2013 update. *Clin Pharmacol Ther* 93:324–325, 2013.

In references 77 and 356, dosing recommendations are provided for azathioprine, mercaptopurine, and thioguanine based on the thiopurine methyltransferase genotype.

Mesenchymal Stem Cells
IMMUNE RESPONSE CRITERIA
CONCLUSION AND FUTURE DIRECTIONS

The role of the immune system in controlling cancer was subject to debate for decades, reflecting the limited understanding of the immune system at the time and the complexity of tumor immunology. However, over time a wealth of evidence from murine and human studies[1-3] has demonstrated that the immune system can control cancer. Numerous animal models have demonstrated the ability of T cells to reject tumors, revealed the importance of cytokines for antitumor immunity, and showed the susceptibility of immunodeficient mice to tumor formation. Compelling evidence of tumor immunosurveillance in humans is provided by reports of rare spontaneous tumor regressions in persons with melanoma and renal cell carcinoma,[4] particularly after infection,[5] paraneoplastic diseases (which are autoimmune neurologic manifestations of an antitumor response), and the higher incidence of melanoma in patients undergoing chronic pharmacologic immunosuppression after organ transplantation.[6] Pediatric patients with immunodeficiencies are at risk for lymphoma, and posttransplant lymphoproliferative disease (PTLD) is a well-known entity in iatrogenically immunosuppressed patients. The immune system can prevent virus-induced malignancies, eliminate tumor cells via recognition of tumor antigens that distinguish them from “self,” and promptly terminate inflammation to avoid tumorigenesis. However, when the latter process is in disarray, such as in chronic inflammatory conditions and autoimmunity, the immune system is implicated in tumorigenesis. The control of tumor growth by the immune system also applies selection pressure, which may ultimately promote tumor progression. In this process, termed "cancer immunoediting,"[7] cancer cells develop immune escape mechanisms and establish a tumor microenvironment that interferes with antigen presentation, T-cell activation, and differentiation, thereby leading to a gradual loss of control by T cells (Fig. 47-1).[8] An expanding body of preclinical and clinical experiences has established that the immune system can be manipulated in increasingly sophisticated ways to prevent, control, or aid in the control of established cancers. Careful selection of the appropriate target antigen(s) and consideration of preexisting immunologic memory are key features in the pursuit of successful immunotherapy. Antigens that are unique to the tumor and absent on healthy tissues often require priming of the immune system but possess the advantage that the induced antitumor response is unlikely to have autoimmune adverse effects. In the case of antigens that are present or overexpressed on tumor cells but are also detectable in some healthy tissues, depletion of T-cell clones with high avidity to the antigen may have polarized existing memory T cells toward tolerance. In this scenario, effective

Figure 47-1 The concept of cancer immunoediting. Malignant transformation can be triggered by multiple insults, including inherited or acquired genetic mutations, exposure to radiation, carcinogens, infections, and chronic inflammation. Intrinsic tumor suppression mechanisms such as deoxyribonucleic acid repair, apoptosis, and senescence are in place to eliminate transformed cells. The extrinsic tumor suppressor mechanism of cancer immunoediting involves both the innate and adaptive arms of immunity and contributes to the control of a developing tumor by recognition of danger signals from immunogenic malignant cells (such as expression of tumor antigens and stress ligands specific for receptors on innate immune cells). If complete elimination of transformed cells is achieved, the person remains free of cancer. However, if rare tumor cell variants or poorly immunogenic cells survive elimination, they may enter a phase of equilibrium during which adaptive immune mechanisms control tumor outgrowth but do not achieve complete elimination. The immune selection pressure may lead to editing of tumor immunogenicity and emergence of tumor escape mechanisms. These mechanisms include (1) loss of antigen or stress ligand expression and major histocompatibility complex–I downregulation to escape recognition by adaptive immunity, (2) desensitization to immune effector mechanisms, and (3) induction of an immunosuppressive tumor microenvironment. If tumor outgrowth is no longer blocked by immune mechanisms, tumor cells emerge to cause clinically apparent disease. *DC,* Dendritic cell; *IDO,* indolamine 2,3-dioxygenase; *IFN,* interferon; *IL,* interleukin; *MDSC,* myeloid-derived supressor cell; *NK,* natural killer cell; *NKT,* natural killer T cell; *PD-1,* programmed cell death–1; *PD-L1,* programmed cell death–1 ligand; *TGF-β,* transforming growth factor β; *TNF-α,* tumor necrosis factor-α; *TRAIL,* TNF-related apoptosis-inducing ligand; *Treg,* regulatory T cell. *(Modified from Schreiber RD, Old LJ, Smyth MJ: Cancer immunoediting: integrating immunity's roles in cancer suppression and promotion.* Science *331:1565–1570, 2011.)*

immunotherapy has to break tolerance and is more likely to induce undesired autoimmunity. The clinical use of immunotherapeutic modalities such as monoclonal antibodies (mABs), vaccines against oncogenic viruses, cytokines, and hematopoietic stem cell transplantation (HSCT) has been the standard of care in the prevention, treatment, and supportive care of cancer for many years. More recently, an exciting renaissance in cancer immunotherapy occurred as a result of the success of proof-of-concept clinical trials for a variety of novel immune-modulating strategies. As will be discussed further, these strategies include cellular therapies such as chimeric antigen receptor (CAR) T-cells (CARTs) and the first Food and Drug Administration (FDA)–approved cancer vaccine (sipuleucel-T); blockade of regulatory pathways with anti–cytotoxic T-lymphocyte antigen 4 (anti-CTLA-4) mABs; and antibody-targeted delivery of drugs via immunoconjugates such as brentuximab vedotin and trastuzumab emtansine. Many early-phase immunotherapy trials are being conducted for adult malignancies first and will be discussed when they are applicable. While promising results and toxicity data emerge from adult trials, the benefits of immunotherapy will also increasingly become available to pediatric patients with cancer.

KEY COMPONENTS OF THE IMMUNE SYSTEM AND THEIR RELEVANCE IN CANCER IMMUNOTHERAPY

The immune response can be divided into innate and adaptive immunity to differentiate between an early, generalized response against evolutionarily conserved molecular patterns and a highly specific response that forms fully as a result of exposure to specific antigens. One can also distinguishe a humoral from a cellular arm of the immune system. The humoral arm consists of soluble factors that are secreted by immune cells and includes antibodies and cytokines. The cellular arm encompasses antigen-presenting cells (APCs), phagocytes, lymphocytes, and innate immune cells.

Humoral Arm of the Immune System

Antibodies

B cells have the ability to differentiate into plasma cells and secrete antibodies. B-cell receptors, which represent surface-expressed antibodies against a vast variety of potential antigens, are created by somatic V(D)J-recombination. Subsequent antigen exposure leads to clonal expansion of B cells with the cognate B-cell receptor and facilitates large-scale antibody production. Antibodies consist of two heavy chains (γ, δ, α, μ, or ε) and two light chains (λ or κ). The composition of the heavy chains determines the immunoglobulin (Ig) subclass, which can be IgM, IgG, IgA, IgE, or IgD. These immunoglobulin subclasses have different binding valencies and functions; for example, IgM is produced early in the immune response followed by a class switch to IgG, whereas IgA is predominantly involved in mucosal immunity. Antibodies function by binding to the antigen of their specificity via the antigen-binding fragment (Fab; consisting of one constant and one variable domain from each of the heavy and light chains), thereby marking their target for destruction in a process termed "opsonization." Cellular destruction is mediated by the crystallizable fragment (Fc) component, which is composed of two heavy chains (Fig. 47-2). Depending on the effector cell and type of Fc receptor (FcR), the immune response can be modulated in multiple ways. Activating FcRs contain a cytoplasmic immunoreceptor tyrosine activation motif, whereas inhibitory FcRs signal via an immunoreceptor tyrosine inhibition motif. FcR binding can lead to antibody-dependent phagocytosis (ADP) by macrophages or APCs or cell destruction by natural killer (NK) cells via antibody-dependent cellular cytotoxicity (ADCC). The Fc component can also fix complement, leading to complement-dependent cytotoxicity (CDC). Antibodies can further kill tumor cells by direct induction of apoptosis and blockade of growth factors or other stimulatory signals (Fig. 47-3).

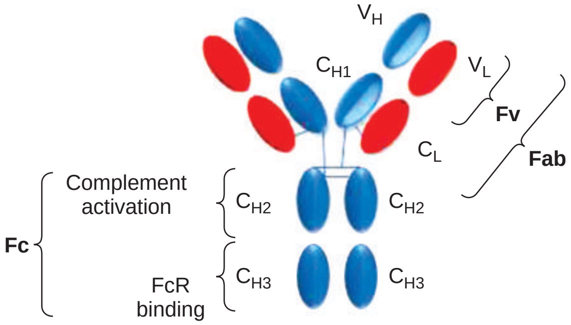

Figure 47-2 Structure of an antibody molecule. Antigen-binding fragment *(Fab)* and crystallizable fragment *(Fc)* regions are distinguished on the basis of proteolytic cleavage by papain. Functionally, the variable region *(Fv)* represents the antibody binding site, whereas the Fc region mediates complement activation and binding to Fc receptors *(FcRs)*. Structurally, one further differentiates heavy chains (*blue*; γ, δ, α, μ, or ε) from light chains (*red*; λ or κ).

Cytokines

Cytokines are soluble proteins that are predominantly produced by leukocytes and carry out intercellular signaling function. Based on their varied functions, they can be classified into interleukins (ILs), interferons (IFNs), chemokines, and hematopoietic growth factors. Several cytokines have been used in cancer immunotherapy either as a single agent or to enhance the effect of other therapeutic agents. Growth factors such as granulocyte-colony stimulating factor (G-CSF) also play an important role in facilitating the neutrophil recovery necessary for compressed chemotherapy regimens, which have led to improved survival for children with multiple types of pediatric solid tumors. Lastly, analysis of the cytokine response triggered by immune therapies is informative in elucidating the mechanism of action and associated toxicities and can guide lifesaving therapeutic interventions, as demonstrated by the successful use of an IL-6 receptor (IL-6R) antagonist in the treatment of cytokine

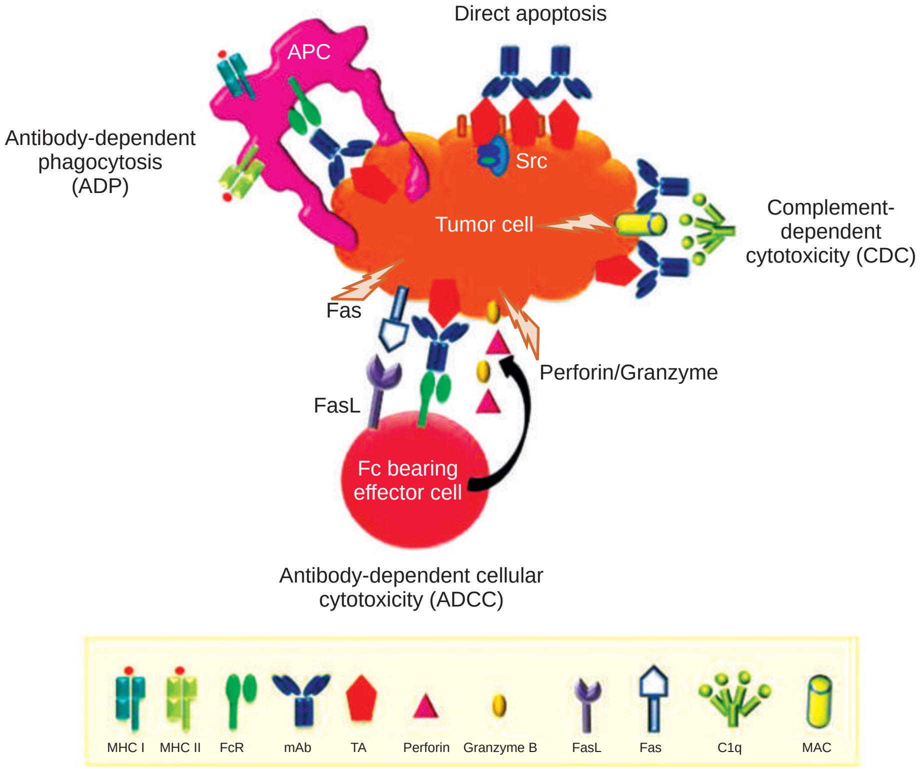

Figure 47-3 Antibody-mediated mechanisms of tumor cell destruction. Antibody-dependent phagocytosis *(ADP)*: Via the antibody-dependent phagocytosis pathway, antibodies entice crystallizable fragment receptor *(FcR)*–bearing phagocytes to take up tumor cells, process a variety of different tumor antigens, and present them in major histocompatibility complex *(MHC)*–restricted fashion to cluster of differentiation (CD)4+ and CD8+ cells. This process can lead to the vaccinal effect of monoclonal antibody *(mAb)* therapy. Antibody-dependent cellular toxicity *(ADCC)*: FcR-bearing effector cells such as natural killer cells can mediate antibody-dependent cellular cytotoxicity via perforin/granzyme B or induce apoptosis via Fas ligand *(FASL)*/Fas after recognition of the crystallizable fragment *(Fc)* portion of the bound antibody. Complement-dependent cytotoxicity *(CDC)*: The C1q protein of the complement system binds to antigen : antibody complexes on the tumor cell surface and causes activation of the complement cascade, resulting in formation of the membrane attack complex *(MAC)* and tumor cell lysis. Direct apoptosis: Cross-linking of antibody molecules and tumor antigens *(TAs)* in the lipid raft can activate signaling pathways involving Src kinases that mediate direct apoptosis. *APC,* Antigen-presenting cell.

release syndrome associated with cluster of differentiation (CD)19-CAR therapy.

Cellular Arm of the Immune System

T Cells

T cells are a major component of the adaptive immune system (Fig. 47-4). They are derived from bone marrow, but in contrast to B cells, they travel to the thymus to undergo V(D)J-recombination of their T-cell receptors (TCRs), editing, and maturation. Somatic recombination of the α- and β-chains of the TCR results in the incredibly diverse T-cell repertoire from which clonal expansion can occur upon encounter of a specific antigen. To prevent autoimmunity, TCRs specific for “self” undergo negative selection in the thymus but also are subject to regulatory mechanisms in the periphery. Generation of an adaptive antitumor response begins with capture of tumor antigens by dendritic cells (DCs) in the peripheral tissues. DCs then travel to the draining lymph nodes, where they interact with T cells. Successful activation of a T-cell response (T-cell priming) requires presentation of the antigen on major histocompatibility complex class I (MHC-I) or class II (MHC-II) molecules for TCR-mediated recognition (signal 1), as well as a costimulatory signal (signal 2). Classically, the costimulatory signal is delivered to CD28 on T cells via the B7 family (CD80 and CD86) on APCs, but many other costimulatory molecules have been identified. The absence of costimulation leads to anergy. T cells may also receive inhibitory signals via CTLA-4, programmed death 1 (PD-1), and various other receptors, which play a physiologic role in terminating an immune response. The tumor microenvironment exploits some of these mechanisms to escape immune surveillance by MHC downregulation, as well as expression of inhibitory ligands such as PD-1 ligand (PD-L1). The discovery and characterization of other modulatory signaling pathways is ongoing and will continue to be a platform for therapeutic intervention.

T cells express CD3 and are divided in CD8+ cytotoxic T lymphocytes (CTLs) and CD4+ helper T cells. DCs can process and present antigens via MHC-I and MHC-II pathways. CD8+ CTLs are generally activated via MHC-I. This pathway predominantly processes antigens derived from the cell itself (such as viral antigens), but it can also

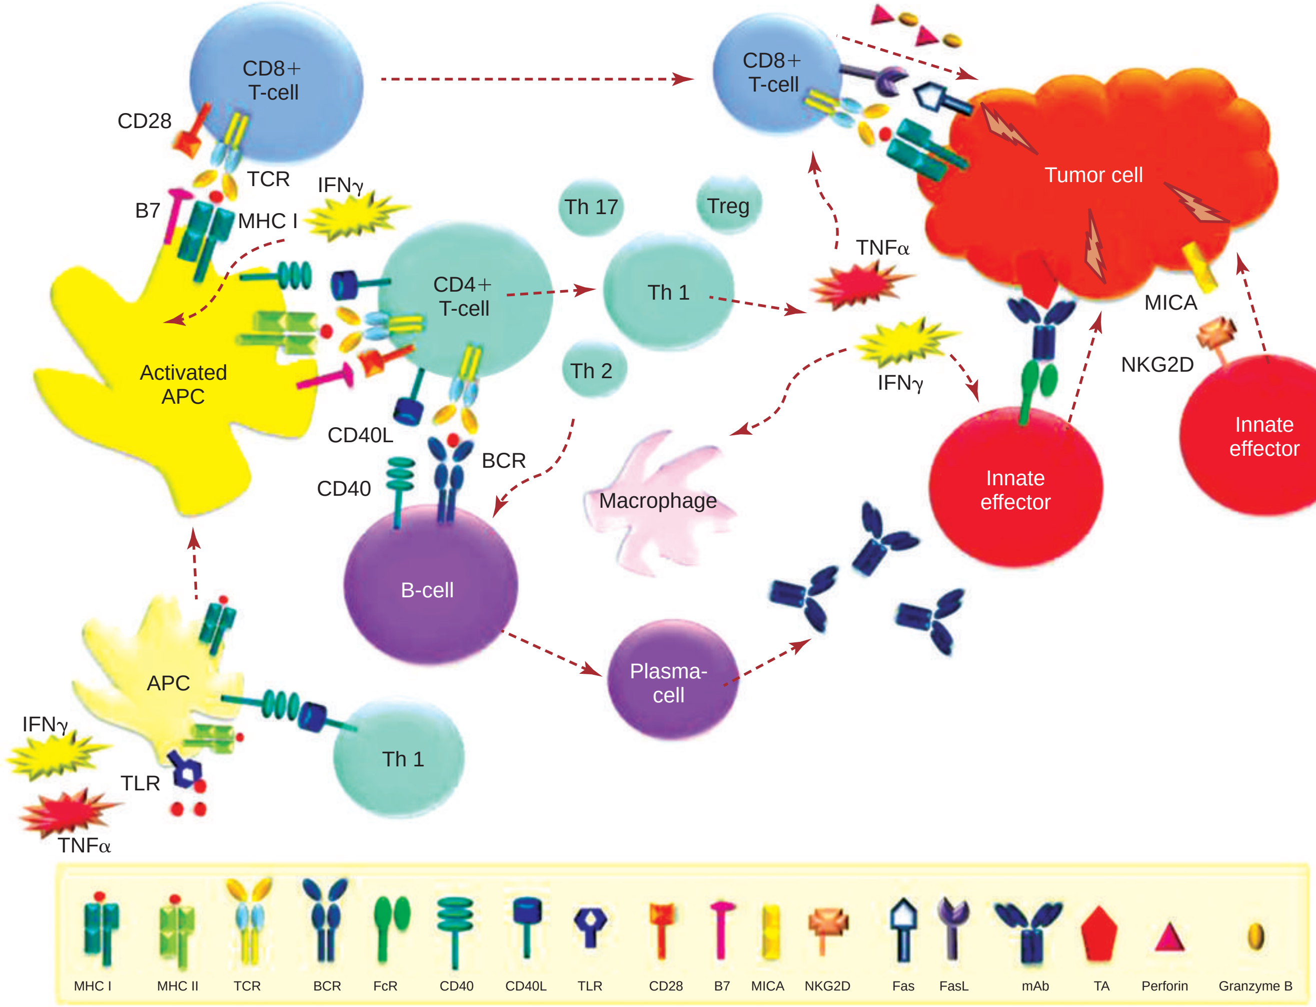

Figure 47-4 Antitumor effects of the immune system. Innate effector cells (such as natural killer cells) are regulated by a system of activating and inhibitory receptors and often recognize major histocompatibility complex *(MHC)*-I or MHC-I–related molecules that are upregulated by cells under the stress of malignant transformation. They are capable of rapid killing of tumor cells or mediation of apoptosis upon recognition of such ligands. They also mediate antibody-dependent cellular toxicity via interaction of their crystallizable fragment receptor *(FcR)* with the Fc portion of antibodies directed against tumor antigens *(TAs)*. Initiation of the adaptive immune response to tumors relies on TA uptake by an antigen-presenting cell (APC) in the context of appropriate maturation signals such as Toll-like receptor *(TLR)* signaling, cluster of differentiation (CD)40/CD40L interaction with CD4+ T cells, and cytokines. In its activated state the APC presents TAs on MHC molecules and provides the necessary costimulatory signals (e.g., CD80/CD86, also referred to as B7) to activate a T-cell response in lymph nodes. Via the MHC-I pathway, APCs prime CD8+ cytotoxic T lymphocytes (CTLs), which then clonally expand, recognize the TA on tumor cells via their cognate T-cell receptor *(TCR)*, and mediate tumor cell lysis. APCs present antigens to CD4+ helper cells via MHC-II molecules. CD4+ T cells do not directly partake in tumor cell destruction but provide help to other immune cells. They are polarized toward functionally distinct subtypes. T helper *(Th)*1 cells mediate tumor immunity through production of cytokines such as interferon *(IFN)*-γ and tumor necrosis factor *(TNF)*-α, which enhance macrophage and CTL functions, and provision of CD40L signals that enhance APC maturation. Th2 cells are crucial for the induction of B-cell responses and antibody production against TAs. Regulatory T cells *(Tregs)* are immunosuppressive, and their presence in the tumor microenvironment dampens a vigorous antitumor immune response. *BCR,* B-cell receptor; *FasL,* Fas ligand; *mAb,* monoclonal antibody; *MICA,* MHC class I–related chain A.

present antigens taken up by the cell through a mechanism referred to as cross-presentation. MHC-I is present on all nucleated cells, and upon recognition of the MHC-restricted cognate antigen on a tumor cell, primed CD8+ CTLs mediate tumor cell death by virtue of releasing perforin/granzyme B or by inducing apoptosis through interactions of death receptors such as Fas/Fas ligand. MHC-II expression is limited to APCs such as DCs, macrophages, and B cells, which process phagocytosed antigens and activate CD4+ T cells via the MHC-II pathway. CD4+ T cells do not generally directly mediate tumor cell lysis, but they critically support and influence the immune response by producing cytokines and providing “help” to CD8+ T cells and B cells via CD40 signaling. Depending on the polarization of their cytokine profile and function, CD4+ helper T cells are divided into Th1, Th2, Th17, and follicular helper T-cell subtypes and regulatory T cells (Tregs). Th1 responses are characterized by proinflammatory cytokines such as IFN-γ and tumor necrosis factor (TNF)-α, which enhance macrophage and CTL function and promote secretion of immunostimulatory cytokines, such as IL-12 by APCs. Th2 responses are essential for antibody production and class switching of B cells, are involved in allergic responses, and produce an array of cytokines such as IL-4, IL-9, IL-10, and IL-13 that contribute to eosinophil and mast cell activation. The Th17 subset was only described relatively recently. Although it is involved in the pathogenesis of autoimmune and inflammatory diseases, it may also play an important role in tumor immunity.[9] Lastly, Tregs express CD25 and the forkhead box (FOX)P3 transcription factor in addition to CD4+. They serve to inhibit immune activation, induce self-tolerance under physiologic conditions, and notably expand in response to IL-2. Treg blockade or elimination is an important factor in facilitating an effective antitumor immune response, and therapeutic expansion of Tregs may play a role in controlling graft-versus-host disease (GVHD).

γδ T Cells

γδ T cells represent a small subgroup of circulating T cells that function at the interface of innate and adaptive immunity. Their TCR also undergoes somatic recombination and editing but consists of a γδ heterodimer. This subset may recognize specific antigenic determinants via the TCR or by a TCR independent pathway similar to that of NK cells.

Natural Killer T Cells

Natural killer T cells (NKTs) are a unique subset of T cells with a highly restricted TCR repertoire, allowing recognition of certain glycolipid antigens, such as GD2, in conjunction with the nonclassical MHC-I molecule CD1d. They contribute to antitumor immunity as an early source of cytokine production, resulting in activation of other effector cells. Higher numbers of tumor-infiltrating NKTs have been associated with improved long-term disease-free survival (DFS) in children with stage IV neuroblastoma.[10] NKTs are thought to inhibit tumor growth by targeting tumor-associated macrophages (TAMs) that have been shown to have clinical significance in neuroblastoma,[11] Hodgkin lymphoma (HL),[12] and other malignancies. NKTs are attracted by the chemokine (C-C motif) ligand 2 (CCL2). *MYCN*, the hallmark of aggressive neuroblastoma, mediates CCL2 repression and therefore reduces NKT infiltration.[13] Via another escape mechanism, TAMs in the neuroblastoma microenvironment produce a different chemokine, CCL20, in response to hypoxia, thereby attracting NKTs into hypoxic traps. IL-15 was shown to protect NKTs from the inhibitory effects of hypoxia and enhances antimetastatic activity of NKTs.[14]

NK Cells

NK cells play a key role in the innate immune response, in an early defense against infection or malignant transformation. NK cells can be phenotypically distinguished from other peripheral blood mononuclear cells because they are CD56+ and lack B-cell (CD19), T-cell (CD3), and monocytic (CD14) markers. Subsets of NK cells also express the FcRs CD16 and CD11b that mediate ADCC and participate in CDC. Contrary to T and B cells, NK-cell receptors do not undergo somatic recombination and do not require recognition of a cognate antigen to mediate cytotoxicity. Traditionally it has been thought that they do not develop immunologic memory, although this paradigm may be changing.[15] Their function is tightly regulated by a complex system of activating and inhibitory receptors, which often recognize MHC-I or MHC-I–related molecules. These interactions provide the basis for the therapeutic exploitation of NK-cell alloreactivity. The key regulators of NK cells are activating and inhibitory killer cell immunoglobulin-like receptors (KIRs), which activate natural cytotoxicity receptors including NKp30, NKp46, and NKp44 and the activation receptor NKG2D. NK cells are capable of rapid killing via degranulation and release of toxic granules, primarily through a perforin and granzyme B–dependent pathway. They can also mediate apoptosis by utilizing Fas ligand or TNF-related apoptosis-inducing ligand (TRAIL) and execute ADCC via their FcRIII (CD16) receptor. NK cells further secrete chemokines such as CCL2 through CCL5, XCL1, and CXCL8. Their clinical significance in pediatrics is underscored by the susceptibility of infants born with NK-cell deficiencies to fulminant viral infections and the NK-cell defects underlying primary hemophagocytic lymphohistiocytosis. NK cells facilitate stem cell engraftment, fight infection, and control cancer, yet they do not cause GVHD. These characteristics make them attractive therapeutic candidates for adoptive NK-cell therapies.

Dendritic Cells

Dendritic cells (DCs) represent a small subset of peripheral blood mononuclear cells (1% to 2%). They are mobile sentinels that collect antigen from peripheral tissues and carry it to the secondary lymphoid organs to activate T cells. DCs are termed “professional APCs” based on their ability to process and present antigenic peptides on MHC-I or MHC-II molecules. In steady state, they reside in the periphery in an immature state and play an important role in maintaining tolerance by taking up self-antigens. Successful T-cell activation requires DC activation. Upon activation, DCs upregulate MHC molecules, costimulatory molecules (which provide the second signal for T-cell activation), and chemokine receptors (which enhance homing to lymphoid organs) and secrete inflammatory cytokines such as IL-12.[16] DC activation can occur in response to a variety of signals, such as the receipt of exogenous and endogenous danger signals via Toll-like receptors (TLRs), which recognize evolutionarily conserved molecular patterns from products of damaged or dying cells and from pathogens.[17] DCs are also matured by proinflammatory cytokines secreted by other cells (e.g., innate effectors) or by CD40 ligation. In addition, DCs are important in launching humoral immunity, partly because of their capacity to directly activate B cells.[18]

Myeloid DCs and plasmacytoid DCs are the two main subsets among various other DCs. They express high levels of human leukocyte antigen (HLA)-DR (MHC-II), but they differ in their expression of CD11c (myeloid DCs), CD123 (plasmacytoid DCs), and TLRs, among other markers. DCs are critical regulators of adaptive T- and B-cell responses and are central to the development of successful tumor vaccines. Because of their low abundance in the peripheral blood, sufficient numbers of DCs can be generated in vitro either by expansion of isolated DCs or by generation from monocytes using cytokine cocktails. DCs further play a role in the pathogenesis of GVHD and are required for full graft-versus-leukemia (GVL) effects, and thus their therapeutic manipulation is of relevance in HSCT.

Neutrophils

Neutrophils are crucial to the rapid destruction of pathogens, particularly bacterial, fungal, and certain parasitic organisms, as evidenced by the high risk of sepsis during periods of neutropenia in the oncology population. However, neutrophils also contribute to antitumor activities of the immune system. Through their FcRs, they can be involved in ADCC-mediated tumor destruction. In addition, neutrophil activation at sites of the tumor via administration of cytokines such as GM-CSF can play a role in tumor cell degradation and enhance antigen presentation.[19]

Monocytes/Macrophages

Monocytes are myeloid-derived phagocytic cells that differentiate into resident macrophages upon recruitment into tissues. Macrophages are able to ingest apoptotic cells and opsonized cells via their FcRs. Aside from their role in clearing cellular debris, they are able to present antigenic peptides of the digested cells in an immunogenic way. Activated macrophages prominently secrete cytokines such as IL-12, which may be critical in activating local immune responses by NK cells and T cells. Macrophages were originally classified into M1 (proinflammatory) and M2 (antiinflammatory) macrophages according to their polarization status. Although this classification remains conceptually helpful, it is now clear that tissue macrophages display a high degree of functional and phenotypic plasticity in response to changing microenvironmental stimuli and that M1 and M2 polarization represent extremes of a continuum of activation states. Increasing evidence indicates that TAMs are implicated in protumor effects and can play a role in tumor initiation, progression, and distant metastasis.[20,21] Limited evidence suggests that myeloid-derived suppressor cells develop from a common myeloid progenitor without a monocytic intermediate and have predefined immunosuppressive properties, whereas monocytes lack suppressive activity in steady state and acquire this function in response to certain stimuli. In persons with cancer, the majority of studies support an association between high TAM density and poor clinical outcome, as has been demonstrated in several malignancies, including neuroblastoma.[11,12] However, TAM function in tumor immunity appears to be dynamic and heterogeneous depending on the tumor type, tumor progression, location within the tumor, and perhaps most importantly, polarization of the TAM. In this regard, increased density of M2-like TAMs is a marker of poor prognosis, whereas the presence of M1-like subsets is advantageous. Based on these findings, subpopulations of TAMs are now being explored as new therapeutic targets.[20]

TARGET ANTIGENS IN CANCER IMMUNOTHERAPY

Tumor antigens (TAs) are molecules that enable the recognition of tumors by components of the immune system. A wide array of target antigens have been identified and may be classified into various subgroups according to their origins. Tumor-specific antigens are epitopes that are found exclusively on malignant cells. This group includes proteins arising from mutated oncogenes, clonally rearranged immunoglobulin genes, and oncoviral gene products. Tumor-associated antigens are expressed on some healthy and malignant tissues alike. Tumor-associated antigens may arise from overexpressed normal proteins, oncofetal proteins, lineage-restricted markers, histocompatibility molecules, and proteins that are normally expressed in immune-privileged sites.

Antigens Arising from Genetic Alterations

A number of malignancies are associated with specific genetic mutations or translocations, resulting in the synthesis of novel proteins that are foreign to the host's immune system, thereby offering the potential of immune recognition while sparing healthy tissues. Commonly they are drivers of or contribute to tumorigenesis, as is the case for oncogenes or mutated tumor suppressor genes, but they may also arise from mutations not directly involved in the neoplastic process. A variety of malignancies express gene products derived from mutated tumor suppressor genes, such as *p53* or *ras*. Examples of antigens derived from mutated oncogenes include the EWS-FLI fusion protein resulting from the t(11:22) translocation characteristic of Ewing sarcoma and the p210 and p190 products of the bcr/abl translocation in chronic myelogenous leukemia (CML) and Philadelphia chromosome–positive acute lymphoblastic leukemia (ALL), respectively.

Oncoviral Proteins

Viral infections play a causal role in several malignancies and give rise to immunogenic viral proteins that can be recognized and eliminated by the immune system. This process is underscored by the fact that immunosuppressed persons, particularly those with impairment of T-cell immunity, have a higher propensity to develop Epstein-Barr virus (EBV)–associated lymphomas and human papillomavirus (HPV)–associated skin and cervical cancers. Examples of oncoviral proteins are the expression of the EBV antigens EBNA-1, EBNA-3, LMP-1, and LMP-2 in PTLD and some lymphomas and the papillomavirus E6 and E7 proteins in cervical carcinomas.

Clonally Rearranged Immunoglobulin Genes

Surface immunoglobulin is a marker of B-cell maturity and is present in mature B-cell non-Hodgkin lymphomas (NHLs) and multiple myeloma. Because surface immunoglobulin expression results from separate somatic recombination events in each B cell, all malignant cells in a monoclonal B-cell malignancy express the clonally unique immunoglobulin variable region, or idiotype. Immunoglobulins are proteins and can therefore be immunogenic and lead to the development of idiotype vaccines. Another approach to targeting this group of TAs includes the generation of anti-idiotype mABs in mice, which in turn are immunogenic and amplify the immune response upon administration to the patient as a type of vaccine.

Altered Glycolipid and Glycoprotein Antigens

Most human tumors express higher levels or abnormal forms of surface glycoproteins and glycolipids, which serve as targets for immunotherapy. Some aspects of the malignant phenotype of tumors, including tissue invasion and metastatic behavior, may reflect altered cell surface properties as a result of the abnormal glycolipid and glycoprotein synthesis. Most of these epitopes are not exclusively expressed on tumors but are present at higher levels on cancer cells compared with healthy tissues. Examples of such glycolipids are GD2, which is expressed in neuroblastoma and some osteosarcomas, as well as GM2, GD2, and GD3 in melanomas. These molecules are actively being explored in vaccination strategies, and mABs against the carbohydrate groups or peptide cores of such molecules have been generated and clinically used with success.

Oncofetal Antigens

Oncofetal antigens are proteins that are expressed at high levels in cancer cells and during normal fetal development, but not in adult tissues. Alpha-fetoprotein expression in hepatoblastomas and germ cell tumors and carcinoembryonic antigen in colorectal cancer are examples of aberrant expression of fetal antigens. Although they are largely utilized as biomarkers, they are also being explored as targets of CART therapy.

Products of Genes That Are Selectively Expressed in Immune-Privileged Sites

An interesting group of antigens are the so-called "cancer-testes antigens." These nonmutated proteins arise from germline-associated genes that are preferentially expressed in immune-privileged sites such as the testes and placenta. These antigens include NY-ESO, MAGE, BAGE, and RAGE and are expressed in melanomas and many carcinomas. They are promising targets given their relatively tumor-specific distribution and have been explored in the context of tumor vaccination.

Histocompatibility Antigens

Histocompatibility antigens are of importance in the allogeneic HSCT setting. Because HLAs are widely expressed in normal tissues and are immunologic targets for T-cell responses, donor selection intends to maximize major histocompatibility matches between the donor and recipient to minimize GVHD. However, minor histocompatibility antigens (mHAs) may generate a GVL response both in matched sibling and in unrelated donor (URD) transplantation. mHAs may have tissue restricted expression, such as HA-1 and HA-2, which are expressed only on hematopoietic cells. Such mHAs are particularly appealing immunologic targets because the induced immunologic response will not cause GVHD in nonexpressing tissues.

Molecules That Activate Recognition of the Innate Immune System

Cells of the innate immune system do not require presentation of antigens via MHC molecules but instead have the ability to respond to MHC-I–related ligands, which tissues may express inducibly in association with cell stress, infection, or malignant transformation, thus allowing for a system in which the body alerts the immune system by creating internal danger signals. Such molecules may not be recognized by endogenous T and B cells but can induce potent responses by innate effector cells. The advantage of such danger signals is that they are absent or expressed at very low levels in steady state. In healthy humans, MICA and MICB, which are ligands for the NKG2D receptor on NK cells and CD8+ T cells, are expressed only by intestinal epithelial cells at low levels, likely as a consequence of stimulation by the local bacterial flora. However, these molecules are significantly upregulated in a variety of tumor types[22] and are thus promising targets.

Normal Proteins Overexpressed in Tumor Tissue

Increased gene transcription or amplification of normal genes in tumor cells may result in aberrantly high expression of proteins. Examples include MYCN amplification in high-risk neuroblastoma, overexpression of human epidermal growth factor receptor 2 (Her2/neu) in a subset of breast and ovarian cancers, as well as some sarcomas, and gp100 and MART in melanomas. Because these proteins are also found at lower levels in some healthy tissues, immune tolerance to such antigens may have developed and needs to be overcome by effective immunotherapy.

Lineage-Specific Tumor Antigens

Many tumors express differentiation antigens that are not restricted to the malignant cell but rather to their lineage of origin. Examples include CD19 and CD22 in pre–B-cell ALL (pre–B-ALL), CD33 in acute myeloid leukemia (AML), and prostate-specific antigen (PSA) in prostate cancer. Similar to overexpressed proteins, the utility of these antigens as targets for tumor immunotherapy is highly dependent on the expression pattern on healthy tissues. As such, the B-cell aplasia accompanying CD19-targeted therapies may be transient and can be managed with exogenous administration of immunoglobulin. Similarly, targeting of PSA may be associated with immune destruction of normal prostate cells, yet this destruction is pathophysiologically tolerable. In contrast, lineage-specific antigen expression on vital organs would be prohibitive to this approach.

TUMOR VACCINES

One of medicine's great successes was the introduction of vaccines for the prevention of infectious diseases.

Vaccines that provide protection against oncogenic viruses effectively prevent certain cancers as well. Based on Center for Disease Control and Prevention estimates, approximately 26,000 new cervical cancers each year are attributable to HPV.[23] Therefore the quadrivalent HPV vaccine, which was implemented in 2007 and is recommended for female and male adolescents, has tremendous potential to prevent cervical cancer.[24,25,26] Another example is the prevention of hepatocellular carcinoma by way of hepatitis B virus vaccination.[27] The generation of therapeutic cancer vaccines is much more challenging, given that such vaccines must overcome preestablished tumor tolerance. However, the discovery that patients can harbor CD8+ and CD4+ T cells specific for antigens expressed in their tumors[28] gave rise to the idea that therapeutic cancer vaccines could activate and amplify this preexisting reaction and possibly induce new immune responses. Adjuvants such as keyhole limpet hemocyanin (KLH) or Montanide are important components of cancer vaccines because they act to enhance the immunogenicity of the antigen, activate DCs, and help overcome preexisting tolerance.

Dendritic-Cell Vaccines

Because of the central role of DCs in the orchestration of adaptive immune responses, DCs have been a special focus of tumor vaccination strategies. Immature DCs take up antigen and rely on appropriate maturation signals to effectively prime T cells, whereas antigen presentation by immature DCs leads to immune tolerance. It is essential to consider the complexity of DC biology in the context of DC vaccine design.[29] Delivery of the TA to DCs and provision of maturation signals can be provided ex vivo or in vivo. Because of the low frequency of DCs in the peripheral blood, approaches have been developed to generate inflammatory DCs from monocytes under culture conditions with cytokine combinations such as GM-CSF and IL-4[30] and then pulse them with the desired antigen ex vivo. Such vaccines have been clinically tested for more than a decade,[31] and it has been concluded that they are safe and can induce expansion of circulating tumor-specific CD4+ and CD8+ T cells, with objective and potentially long-lasting responses in some patients.[32,33] Sipuleucel-T, a vaccine based on enriched blood APCs that are briefly cultured with a fusion protein of prostatic acid phosphatase and GM-CSF, was the first tumor vaccine to be approved by the FDA after it demonstrated a prolonged median survival of patients with metastatic prostate cancer in a randomized phase I trial.[34] In pediatrics, the experience has been limited to a few early nonrandomized trials. Administration of tumor lysate/KLH pulsed autologous DCs to children with relapsed solid tumors was well tolerated and demonstrated induction of specific T-cell responses. Significant regression of metastatic sites was observed in one patient, with several other patients having sustained stable disease.[35] In a related approach, patients with metastatic or relapsed sarcomas or neuroblastomas are receiving Treg-depleted autologous lymphocytes in combination with tumor lysate/KLH pulsed DCs ± IL-7 (trial NCT00923351). An initial study demonstrated that consolidative immunotherapy consisting of adoptive T-cell transfer with peptide-pulsed DCs can improve survival compared with historic control subjects when given in a minimal residual disease (MRD) setting of high-risk solid tumors.[36] An ongoing trial of decitabine followed by vaccination with autologous DCs pulsed with overlapping peptides derived from full-length MAGE-A1, MAGE-A3, and NY-ESO-1 antigens may hold promise in the induction of remission of relapsed neuroblastoma[37] or sarcoma (trial NCT01241162).

DCs can also be targeted in vivo by fusing the selected antigen to an antibody directed against a DC surface receptor. This technique has been shown to elicit potent antigen-specific CD4+ and CD8+ T-cell responses.[38] The choice of a DC receptor that is targeted is an important consideration because distinct DC subsets induce different types of T-cell polarization, which determine in part the elicited immune response.[39] The engagement of DC receptors by such targeting antibodies also provides activation signals, which are crucial to avoid the induction of T-cell anergy. In fact, it is now accepted that the adjuvant components of vaccines (even non–DC-based vaccines) primarily act by triggering DC maturation.

The delivery of antigens and adjuvants into the same intracellular DC compartment has been shown to be crucial.[40] Nanovaccines are a promising preclinical technology to achieve synchronized delivery of antigen and adjuvant cargo to DCs. Nanoscale complexes such as polymer-based or lipid-based nanoparticles provide protection against unwanted antigen degradation or systemic immune activation by soluble adjuvants. Upon injection into the skin, nanovaccines are transported to the lymph nodes by cell-based drainage or free interstitial lymphatic flow (depending on particle size), where they are internalized by lymph node resident DCs and generally directed to the MHC-II pathway.[41] Another bioengineering-based approach is now entering clinical trials and involves implantation of absorbable polymer scaffolds, pulsed with tumor lysate and adjuvants, to facilitate DC-based T-cell priming in situ.[42]

Peptide-Based Vaccines

The immunogenicity of peptide epitopes depends on their associations with specific polymorphic variants of MHC molecules, such that a given peptide might only elicit a response in persons with a certain HLA allele. Studies with HLA-restricted peptides thus must be carried out in patients with unique HLA alleles. Given that the population of pediatric patients is small a priori, the exploration of peptide vaccines has been much more feasible in adults who have common malignancies. Largely as a result of a poor understanding of the mechanisms of immunization and the role of DCs, in many early trials patients were unsuccessfully treated with short peptide-based vaccines in the absence of effective adjuvants.[43] Short peptides have pharmacokinetic properties that make them susceptible to rapid clearance in the absence of an adjuvant that can effectively trigger DC maturation and may promote tolerance rather than immunity. A notable exception is the administration of a short-peptide vaccine derived from gp100 in conjunction with

IL-2, which augmented tumor responses and prolonged progression-free survival (PFS) compared with IL-2 alone in persons with advanced melanoma.[44] Longer peptides (~20-mer) require further processing by DCs but have the potential to prime against a greater variety of antigens and capture CD8+ and CD4+ lymphocyte responses more efficiently compared with peptides (10- to 12-mer) that fit the MHC-I antigen-binding groove unedited. A long-peptide vaccine against HPV-16 oncoproteins administered in incomplete Freund adjuvant to patients with vulvar intraepithelial neoplasia proved to have good efficacy, including complete responses in a phase II trial.[45] These favorable results may be based on the selection of viral gene products for vaccination that are more readily recognized as foreign. In contrast, a long-peptide vaccine derived from p53 (a tumor suppressor protein mutated in many cancers), which was delivered in the emulsion-adjuvant Montanide, induced no tumor regressions in patients with advanced ovarian cancer, emphasizing preexisting tolerance and the need to optimize these formulations.[46]

Full-length protein vaccines harbor a wider profile of epitopes, and a diverse set of targets—including two cancer testes antigens, MAGE-A3 and NY-ESO-1—have been explored.[47,48] Phase I and II trials have been conducted with adjuvant-mixed, recombinant MAGE-A3 vaccines in melanoma and non–small cell lung cancer, demonstrating potent antitumor B- and T-cell responses, tumor-specific cell persistence for years after vaccination, and encouraging clinical effects.[49,50] "MAGRIT"—an ongoing large, randomized phase III trial accruing more than 2500 HLA-A2–positive patients with non–small cell lung cancer—is exploring a recombinant MAGE-A3 fusion protein in combination with an adjuvant consisting of a saponin/lipid-A emulsion and TLR4 and TLR9 agonists.[51]

Whole-Cell Vaccines

Whole-cell vaccines contain the broadest range of TAs, including mutated proteins. A meta-analysis of 173 immunotherapy trials involving a variety of solid tumors revealed that patients vaccinated with whole-cell vaccines had low objective response rates that were nonetheless significantly higher than those of patients treated with molecularly defined antigen vaccines.[52] GVAX, a vaccine strategy in which autologous or allogeneic whole tumor cells are engineered to secrete GM-CSF (to activate APCs at the site of vaccination) and are irradiated prior to injection, reached the furthest in clinical development. Phase I trials of GVAX were conducted in adults who had a variety of malignancies.[53] These early-stage trials were not powered to assess clinical endpoints, yet they consistently demonstrated immune cell infiltration at the sites of vaccination, as well as extensive tumor necrosis mediated by dense infiltrates of intratumoral CD4+ and CD8+ lymphocytes and plasma cells. Although some patients had promising results after receiving GVAX in preceding trials, a phase III trial in persons with prostate cancer that used allogeneic tumor cell lines did not demonstrate clinical efficacy.[54] This results indicate that this strategy may be most effective when autologous tumor cells are used or when it is combined with other immune-modulating therapies. Administration of anti-CTLA4-mAb to patients previously immunized with GVAX evoked objective responses of metastatic melanoma with minimal toxicities.[55] Furthermore, administration of GVAX early after allogeneic HSCT for adult AML or myelodysplastic syndrome was shown to be safe and immunogenic,[56] with encouraging responses that have led to further exploration in a randomized phase II study (trial NCT01773395). In a similar approach, a pediatric phase I trial with IL-2-transduced autologous neuroblastoma cells in 10 patients resulted in the generation of antitumor antibodies and increased antitumor cytotoxic activity, which correlated well with clinical responses. This study observed one complete response, one partial response, and three patients with stable disease, of whom one patient entered complete remission (CR) after oral etoposide therapy.[57] In a subsequent study of 21 patients treated with an allogeneic neuroblastoma vaccine engineered to secrete lymphotactin and IL-2, two complete responses and one partial response were induced.[58]

Idiotype Vaccines

The clonal immunoglobulin idiotype, which is displayed on the surface of most malignant B cells, is a patient- and tumor-specific antigen that can be used for therapeutic vaccination. An idiotype vaccine conjugated with KLH and administered with GM-CSF indicated prolonged PFS in one phase III trial, whereas several other trials failed to demonstrate a therapeutic benefit.[59]

DNA Vaccines

Deoxyribonucleic acid (DNA) vaccines consist of viral vectors that encode TAs and are based on the idea that strong immune responses against the viral vaccine components enhance the reactivity to the TA. A phase II trial, PROSTVAC, utilized a recombinant vaccinia virus that encoded PSA along with costimulatory and adhesion molecules with the intention of rendering infected cells into surrogate APCs, followed by administration of a similarly configured fowlpox vector in a prime-boost strategy. For additional immune stimulation, GM-CSF was administered with the vectors. This trial demonstrated a median overall survival (OS) benefit of 25.1 months in the treatment group versus 16.6 in the control group[60] and prompted initiation of a phase III trial.

CYTOKINES

Interferons

IFNs are a class of cytokines that were initially investigated for their ability to interfere with viral infections, and they play an important role in the propagation of an immune response. Clinically meaningful activity of IFN-α has been shown against CML,[61] although its clinical use in CML has largely been abandoned with the advent of tyrosine kinase inhibitors. IFN-α remains a very relevant agent in the adjuvant therapy of high-risk operable melanoma, and high-dose IFN-α has demonstrated a consistent and significant improvement in DFS and OS.[62]

Interleukin-2

IL-2 plays a crucial role in T-cell growth and proliferation. It is primarily produced by CD4+ T cells after antigen stimulation, and to a lesser extent by CD8+ cells, NKT cells, activated DCs, and mast cells. IL-2 transcription is mediated by multiple transcription factors, including the nuclear factor of activated T cells (NF-AT) family proteins, AP-1 and NF-κB. The immunosuppressive drugs cyclosporine and tacrolimus act by blocking NF-AT translocation to the nucleus. The IL-2 receptor (IL-2R) is composed of an α, β, and γ chain. The IL-2R β chain is shared with IL-15, and the common γ chain receptor (γcR) is shared with six other cytokines. The crucial role of IL-2 in T-cell growth is evidenced by the severe combined immunodeficiency phenotype of patients with γcR defects. IL-2 preferentially promotes differentiation of Th1 and Th2 cells while inhibiting Th17 and follicular helper T-cell development, yet it can promote Th17 expansion once polarization has occurred. Importantly, IL-2 also drives the development of Tregs, which promote tolerance, and is essential for activation-induced cell death, an important regulator of T-cell homeostasis. Besides its potent effect on T cells, IL-2 induces proliferation and cytolytic activity of NK cells and promotes B-cell proliferation and antibody production.[63]

Clinical administration of IL-2 in an effort to activate immune cells has been in use for many years, with FDA approval in 1992 for metastatic renal cell carcinoma and in 1998 for metastatic melanoma.[64] In a small subset of 5% to 10% of patients with these malignancies, IL-2 treatment has resulted in long-term CRs, and the addition of adoptive therapy approaches have improved cure rates for metastatic melanoma to a range of 20% to 40%.[65] A limitation of IL-2 is its toxicity, including the propensity for severe capillary leak syndrome.

In pediatrics, a randomized children's oncology group trial of 289 children with AML in CR1 who received either no further therapy or two short courses of IL-2 after intensive chemotherapy did not show improvement in DFS or OS.[66] However, IL-2 administration plays a role in the treatment of high-risk neuroblastoma, where it is used in conjunction with anti-GD2 mAb therapy, GM-CSF, and isotretinoin, an approach that has led to significant improvements in outcome.[67] The rationale underlying coadministration of IL-2 is the promotion of ADCC via FcRs of IL-2–activated NK cells and macrophages, which demonstrated an enhanced antitumor effect in murine models compared with IL-2 or mAb alone.[68]

As the effects of IL-2 on Tregs have become more clearly delineated, exogenous administration of IL-2 and therapeutic interventions that may prompt high levels of endogenous IL-2 production are being considered carefully. In fact, the tolerance-inducing aspect of IL-2 administration is now being explored for the treatment of GVHD. It has been shown that daily low-dose IL-2 can be safely administered in patients who have chronic GVHD, leading to a preferential and sustained Treg expansion in vivo and ameliorating chronic GVHD symptoms in a substantial portion of patients.[69,70] Furthermore, IL-2 remains an invaluable tool for the in vitro expansion and preparation of adoptive T-cell therapeutics.

Interleukin-7

IL-7 is produced by nonhematopoietic stromal cells and in small amounts by DCs but is not produced by T cells, B cells, or NK cells. It signals through the IL-7 receptor (IL-7R), a heterodimer consisting of IL-7Rα and the γcR, and mediates antiapoptotic and costimulatory proliferative signals through activation of phosphatidylinositol 3-kinase (P13K) and Janus kinase (JAK) signal transducers and activators of transcription (STAT), as well as antiapoptotic pathways such as B-cell lymphoma–2 (B-CL2). IL-7 is required for normal human T-cell development as demonstrated by the absence of T cells in patients with severe combined immunodeficiency as a result of mutations in the IL-7Rα or γcR, and it may play a role in normal B-cell development. Further, IL-7–mediated signaling in DCs has been implicated as a regulator of peripheral CD4+ T-cell homeostasis. Contrary to typical activation cytokines that do not act on resting T cells, IL-7 primarily affects naive T cells, which then downregulate IL-7R upon T-cell activation. An exception to this rule occurs during primary immune responses when IL-7R expression is maintained on a small subset of T cells destined to enter the central memory pool. Whereas IL-7 is continuously available in secondary lymphoid organs, plasma IL-7 is a limited resource and increases in lymphopenic states as a result of decreased use, thereby enhancing T-cell proliferation.[71] In preclinical models, IL-7 therapy augments antigen-specific T-cell responses after vaccination and adoptive cell therapy.[72,73] It also facilitates immune reconstitution in lymphopenic settings, largely via thymus-independent homeostatic expansion of peripheral T-cell populations,[74,75] and has been implicated in antagonizing inhibitory networks.[76]

In light of the preclinical promise, several clinical trials are using recombinant human IL-7 (rhIL-7) to treat patients with malignancies, chronic viral infections, and idiopathic CD4+ lymphopenia, as well as after HSCT. In the first adult human trial of patients with refractory malignancies, rhIL-7 was well tolerated apart from mild toxicities. After an initial decline in the numbers of circulating lymphocytes, IL-7 showed consistent biologic activity with substantial increases of CD8+ and CD4+ cells in the peripheral blood, as well as in spleen and lymph nodes, whereas proliferation rates of Tregs inversely correlated with IL-7 treatment. Notably, rhIL-7 preferentially induced the nonclonal proliferation of naive T cells, resulting in broadening of the TCR repertoire diversity without increasing thymopoiesis. However, in this subset of highly refractory patients, no significant antitumor effects were observed.[77] The first trial that used rhIL-7 after allogeneic HSCT was performed in recipients of T-cell–depleted grafts, given that IL-7 had boosted alloreactive T cells and GVHD in murine models.[78] IL-7 was well tolerated, with only one case of acute GVHD of the skin. In contrast to other clinical scenarios, IL-7 in the posttransplant setting preferentially expanded effector memory T cells rather than naive T cells but increased

TCR diversity and functional viral-specific T cells.[79] Further studies are needed to determine whether these effects translate clinically into reduced morbidity and mortality and protection from infection. In pediatric sarcomas, IL-7 therapy is currently being explored in the context of DC vaccination (trial NCT00923351).

Interleukin-15

IL-15 was discovered in 1994 and has pleiotropic immune-enhancing properties. It is thought to be critical for the stimulation and differentiation of NK cells, NKTs, and memory CD8+ T cells. It also promotes proliferation and differentiation of CD4+ T cells, nonmemory CD8+ T cells, and B cells; it further enhances cytolytic activity of CD8+ T cells and induces DC maturation and immunoglobulin synthesis by B cells. Although IL-15 messenger ribonucleic acid (mRNA) is expressed by a large number of tissues, the detection of IL-15 protein is largely limited to DCs and monocytes/macrophages. Free soluble IL-15 is limited, indicating tight regulation of this proinflammatory cytokine. The composition of the heterotrimeric IL-15 receptor (IL-15R) and the main signaling mechanism of IL-15 via presentation in trans are unique. IL-15 shares the β chain (IL-2Rβ/IL-15Rβ) and γcR chain with the IL-2R and signals through these domains via the JAK1/JAK3/STAT5 signaling pathway. Contrary to IL-2 signaling, where the IL-2Rα domain assembles with the IL-2Rβ and γc subunits on the recipient cell, the IL-15Rα domain is located on APCs, binds IL-15 with high affinity, and then presents IL-15Rα–bound IL-15 to the IL-15Rβ/γcR heterodimer on NK or T cells in trans. IL-15 is also thought to have minor signaling pathways that involve direct binding to the IL-15Rβ/γcR as well as binding to IL-15Rα on the target cell and presentation in cis to the IL-15Rβ/γcR on the same target cell.[80] Unlike IL-2, IL-15 does not stimulate immunosuppressive Tregs and has an antiapoptotic effect on T cells. Preclinical and clinical data suggest a dual role for IL-15. Through the link between inflammation and cancer, it has been suggested that IL-15 plays a proleukemic role in hematologic malignancies. In adults with pre–B-ALL, IL-15 expression was associated with an inferior 5-year relapse-free survival (RFS), as well as mediastinal and lymph node involvement.[81] In children without central nervous system involvement at diagnosis, high IL-15 expression levels were associated with a higher risk of central nervous system relapse.[82] A phase I clinical trial blocking IL-15 presentation in trans for patients with T-cell large granular leukemia was well tolerated but showed no responses.[83] On the other hand, evidence for a protective role of IL-15 through enhanced tumor immunosurveillance is provided with the antitumor effects of IL-15 in several preclinical tumor models.[84,85] Ongoing phase I trials for adults with advanced melanoma are investigating the administration of rhIL-15, either alone or after transfer of tumor-infiltrating lymphocytes (TILs; trials NCT01021059 and NCT01369888). IL-15 is also used for ex vivo preparation of cellular immunotherapies such as in a pediatric trial of haploidentical HSCT and IL-15–stimulated NK cells for refractory solid tumors (trial NCT01337544).

ANTIBODY-BASED IMMUNOTHERAPY

The specific recognition of surface antigens on pathogens or tumor cells was first conceptualized by Paul Ehrlich more than a century ago. In contrast to cellular immunotherapy, which often requires costly and individualized preparation, antibody-based immunotherapy is feasible for off-the-shelf use and thus is more cost effective. Antibody-based therapy may rely on recognition of TAs or interfere with tumor cell growth by disrupting negative regulatory and survival pathways as well as ligand receptor–dependent cell growth. Unconjugated antibodies predominantly function by recruiting other immune effector cells and initiating pathways such as ADCC, CDC, ADP, and direct apoptosis. Via the ADP pathway, antibodies entice APCs to take up not only the targeted antigen but also a variety of tumor contents that are processed to induce T-cell responses in MHC-restricted fashion.[86] This effect is termed the "vaccinal effect" of antibody therapy because it promotes not only immediate tumor cell death, but also vaccinelike antitumor effects with ensuing humoral and cellular immunologic memory. Clinically this effect has been shown to be relevant in solid tumors and lymphomas.[87] Although conventional antibodies activate innate effector mechanisms, they do not trigger T-cell immunity directly. The development of bispecific antibodies represents a promising approach to recruit and activate T cells directly at the site of the tumor cell by providing specificity not only to the TA but also to CD3 (Fig. 47-5).

Unconjugated Antibodies

Rituximab, a genetically engineered chimeric mouse antihuman CD20 mAb, was the first mAb to be approved by the FDA for the treatment of cancer in 1997. The murine Fab domain of rituximab binds CD20 on mature B-cell malignancies and healthy B cells, and the humanized Fc domain mediates effector functions. The mechanism of cytotoxicity is primarily via ADCC and CDC, although rituximab has also been shown to sensitize resistant lymphoma cells to chemotherapy and Fas ligand–induced apoptosis,[88] which led to its synergistic use with chemotherapy regimens in clinical practice. It may also have a vaccinal effect, leading to T-cell priming and lasting antilymphoma immunity. Rituximab is now a well-established component of therapeutic regimens for adult CD20+ NHL[89,90] and chronic lymphocytic leukemia (CLL) in the United States and Europe.[91] CD20 is expressed by almost all cases of pediatric B-cell NHL,[92] yet clinical experience with rituximab in pediatric lymphomas is still limited and in evolution. Pediatric randomized controlled trials of antibody therapy for B-cell lymphoma have not been published, but a limited number of phase I and II studies suggest a low incidence of adverse effects and encouraging response rates.[93] In a study of 38 children with stage III/IV B-cell NHL who were treated with a combination of FAB/LMB96 chemotherapy and rituximab, the 3-year event-free survival (EFS) and OS was 95%.[94] As rituximab is studied further in the pediatric population, it may improve outcomes

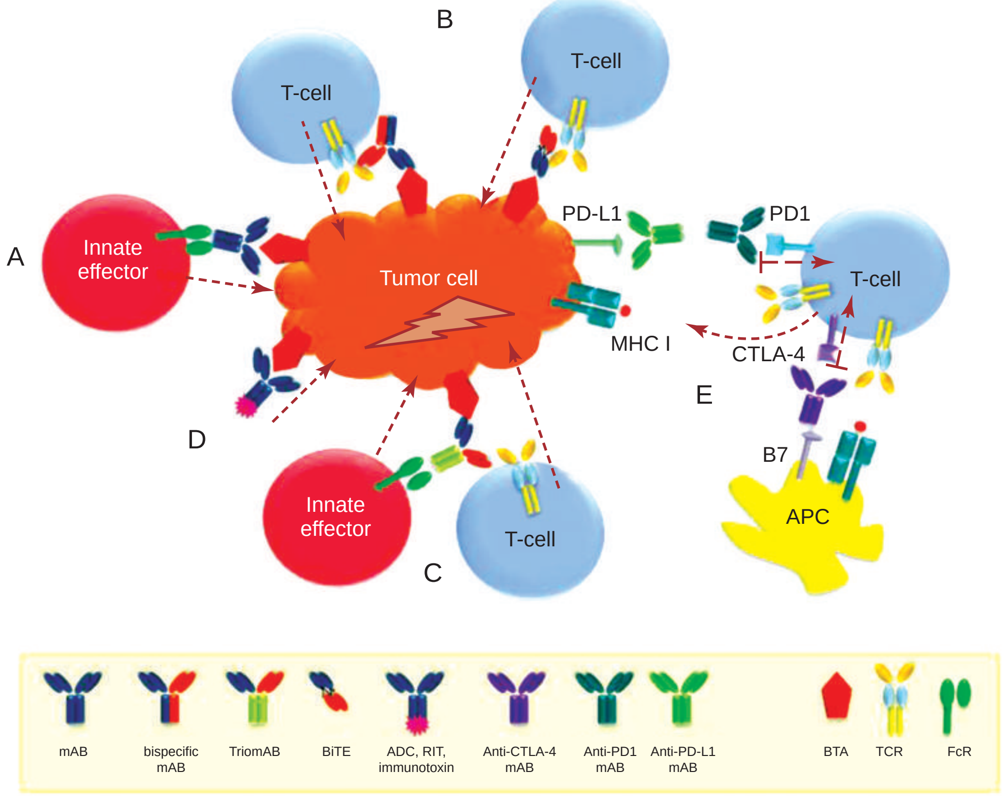

Figure 47-5 Mechanisms of antibody-based immunotherapy approaches. Various iterations of monoclonal antibodies *(mABs)* have been developed for the treatment of cancer. **A,** Unconjugated mABs bind to their target and engage effector cells (see Fig. 47-4). **B,** Bispecific mABs and bispecific T-cell engagers *(BiTEs)* are engineered to bind to the tumor antigen *(TA)* and engage cluster of differentiation (CD)3 on cytotoxic T lymphocytes (CTLs), thereby activating CTLs against tumor cells, independent of their T-cell receptor *(TCR)* specificity. **C,** Triomab antibodies *(TriomABs)* bind to TA and CD3 but also recruit natural killer cells and macrophages via their crystallizable fragment receptor *(FcR)*. **D,** Immunoconjugates deliver cytotoxic agents directly to the target cell. **E,** Antagonistic mABs to cytotoxic T-lymphocyte antigen 4 *(CTLA-4)*, programmed death–1 *(PD-1)*, programmed death–1 ligand *(PD-L1)*, or programmed death–2 ligand block ligand-receptor interactions that otherwise deliver inhibitory signals to the T cell and unleash their antitumor potential. *ADC,* Antibody drug conjugate; *APC,* antigen-presenting cell; *MHC,* major histocompatibility complex; *RIT,* radioimmunotherapy. *(Modified from Baumeister SH, Dranoff G: Principles of targeted immunotherapy. Translational cancer research: molecular therapeutics. In Kurzrock R, editor:* Targeted therapy in cancer, *Wiley Publications, Hoboken, N.J., in press.)*

both for newly diagnosed patients and patients who have had a relapse or have refractory disease, and facilitate chemotherapy regimens with reduced toxicity. Rituximab further finds application in the treatment of PTLD, either as a single agent or in combination with low-dose chemotherapy.[95] Isolated reports also indicate its utility in the treatment of pediatric paraneoplastic syndromes.[96] It should be emphasized that rituximab temporarily depletes healthy B cells, and thus patients may require immunoglobulin replacement.

Specific to the treatment of pediatric high-risk neuroblastoma is a highly effective unconjugated mAb against the disialoganglioside GD2. When immunotherapy (consisting of ch14.18 anti-GD2 mAb in conjunction with IL-2 and GM-CSF) was administered with isotretinoin after standard intensive multimodal therapy in a phase III trial, 2-year EFS increased dramatically to 66% versus 46% and OS increased to 86% versus 75%.[67]

Also noteworthy is trastuzumab, an antibody against HER2, which is approved by the FDA for the treatment of HER2-overexpressing breast cancer and gastric adenocarcinoma.

Bispecific Antibodies

Staerz and colleagues[97] first introduced the concept of bispecific antibodies to engage CTLs for cancer cell lysis. Such antibodies have dual specificity for both CD3 and the TA of interest, thereby bringing CTLs in close proximity to the tumor cell and facilitating the killing of tumor cells, regardless of the T-cell's TCR specificity. Increasingly sophisticated constructs have been developed with time. Bispecific T-cell engagers (BiTEs) can be distinguished from other bispecific constructs by their high potency at picomolar range and support of serial lysis at low effector-to-target ratios. BiTEs against multiple different target antigens including CD19, GD2, epithelial cell adhesion molecule (EpCAM), Her2/neu, epidermal growth factor receptor (EGFR), carcinoembryonic antigen (CEA), CD33, ephrin type A receptor 2 (EphA2), and melanoma-associated chondroitin sulfate proteoglycan (MCSP) have been constructed. Conventional EGFR antibodies such as cetuximab can mediate an ADCC effect via FcRs but appear to act predominantly by blocking EGFR, based on analyses showing that patients with downstream mutations in *KRAS* and *BRAF* genes do not have an overall survival advantage.[98] EGFR-BiTE antibodies, however, can activate T cells via CD3 when engaging a tumor cell and have been shown to lyse even KRAS-mutated colorectal cancer cell lines.[99] EpCAM is frequently expressed on human adenocarcinomas and some squamous cell carcinomas, but also on cancer stem cells.[100,101] MT110,[102] an EpCAM BiTE, is being tested in a phase I trial for lung, gastrointestinal (GI), breast, ovarian, and prostate cancers (trial NCT00635596). Blinatumomab, a CD19 BiTE that targets B-cell malignancies, first demonstrated efficacy in persons with advanced NHL[103] and has shown promising phase II results as a single agent in adult patients with ALL who have persistence or recurrence of MRD, leading to a 80% response rate with elimination of MRD[104] and a 61% hematologic RFS at a median follow-up of 33 months.[105] Of note, some but not all of the patients who experienced a relapse had CD19-negative relapses. As expected, blinatumomab treatment resulted in B-cell depletion, but interestingly, it also resulted in a transient decline followed by a significant expansion of T cells bearing the early activation marker CD69.[106] CD4+ T cells expanded more profoundly than did CD8+ T cells, but Treg numbers generally remained low. A single-arm phase II multicenter international trial is currently evaluating blinatumomab in pediatric and adolescent patients with relapsed or refractory ALL (trial NCT01471782). In the first reported pediatric experience of compassionate blinatumomab use in patients with refractory ALL who had experienced multiple relapses after HSCT, all three patients were able to reach MRD-negative CRs, although only one patient who was able to undergo subsequent HSCT had a lasting remission.[107] From a practical standpoint, blinatumomab is administered as a continuous 24-hour infusion for 4 weeks per 6-week cycle via a portable mini pump. The most prominent adverse effects of blinatumomab include lymphopenia, pyrexia, hypogammaglobulinemia, and hypokalemia, but reversible neurologic toxicities such as seizures and ataxia have been reported. Other BiTEs such as a CD33/CD3 BiTE for AML[108] and BiTEs engaging NK cells via CD16[109] are still in preclinical development.

In yet another iteration, Triomab antibodies are specific for the TA and engage T cells via CD3, but they also recruit NK cells and macrophages via their FcR. Catumaxomab, a Triomab antibody against EpCAM, was approved in Europe in 2009 for the treatment of malignant ascites in a variety of EpCAM+ abdominal tumors, following its success in a phase II/III clinical trial.[110] Other Triomab antibodies are in phase I/II adult clinical trials, such as a CD20 Triomab antibody in the therapy of B-cell lymphoma in conjunction with donor lymphocyte infusion (DLI) after allogeneic HSCT (trial NCT01138579) and ertumaxomab, a Triomab antibody against HER2/neu+ advanced solid tumors (trial NCT01569412). An anti-GD2 Triomab antibody has thus far been tested in animal models of neuroblastoma.[111]

Immunoconjugates

Various immunoconjugates have emerged from the idea that mABs against TAs could be exploited to deliver cytotoxic agents directly to the tumor cell site and minimize systemic adverse effects. In this approach, mABs are linked to radionuclides (radioimmunotherapies), drugs (antibody-drug conjugates, or ADCs), toxins (immunotoxins), enzymes (antibody-directed enzyme prodrug therapy), and cytokines (immunocytokines) to boost the cytotoxic mAb effects on target cells. Two radioimmunotherapies targeting CD20 have been approved by the FDA for adults. Yttrium-90 ibritumomab tiuxetan, approved in 2002, is used in the therapy of follicular NHL or relapsed/refractory low-grade NHL. Iodine-131 tositumomab was approved by the FDA in 2003 and is now indicated in the treatment of CD20+ relapsed or refractory follicular or transformed NHL.[112,113]

A very promising recent ADC, brentuximab vedotin, carries the antimitotic drug monomethyl auristatin E and targets CD30, leading to tumor cell apoptosis. It has shown remarkable efficacy in adults with relapsed or refractory HL or anaplastic large-cell lymphoma (ALCL).[114-116] These results led to accelerated FDA approval for brentuximab in 2011 for the treatment of HL and ALCL; it was the first new drug to be approved for HL in more than 30 years. Brentuximab has also been used successfully prior to allogeneic HSCT, as well as for relapse after allogeneic HSCT.[117,118] Its efficacy in other CD30+ adult malignancies is being tested in the phase II trials NCT01461538 and NCT01421667, and several clinical trials are being conducted to evaluate its safety and efficacy in conjunction with combination chemotherapy as a frontline agent (e.g., trial NCT01060904). In the pediatric population, brentuximab is currently being explored in a phase I/II trial for relapsed or refractory ALCL and HL (trial NCT01492088), but successful single-agent remission induction in a pediatric patient with ALCL who has experienced multiple relapses has been reported.[119] The Children's Oncology Group is planning to evaluate inclusion of brentuximab in the upfront therapy of newly diagnosed patients with classic HL across all risk strata in an effort to improve initial response and minimize radiotherapy, as well as to evaluate administration of brentuximab in conjunction with gemcitabine for relapsed/refractory HL.[120] Cooperative groups are also pursuing evaluation of brentuximab vedotin in combination with standard chemotherapy in children with ALCL.[121] Based on CD30 expression in patients with GVHD,[122] brentuximab is also being investigated as an agent to treat and prevent GVHD (trials NCT01596218 and NCT 01700751).

Trastuzumab emtansine most recently gained FDA approval in 2013 for the treatment of Her2+ metastatic breast cancer. This ADC combines the Her2-targeting antitumor properties of the mAb trastuzumab with the cytotoxicity of the microtubule inhibitory agent DM1, a derivative of maytansine. In a randomized international phase III trial it showed significantly prolonged PFS with less toxicity compared with a standard chemotherapeutic regimen[123] and further compared favorably to trastuzumab and docetaxel in a phase II trial of patients with metastatic breast cancer who had progressed after receiving Her2-targeted therapy with trastuzumab.[124] This drug has not been evaluated in children but may hold promise, given reports of Her2 expression in subgroups of patients with osteosarcoma,[125] Ewing family tumors,[126] neuroblastic tumors, and some Wilms tumors.

Gemtuzumab ozogamicin (GO) is a humanized anti-CD33 mAb conjugated with the anthracycline calicheamicin. It targets CD33, which is expressed in more than 80% of patients with AML. In phase II results of adults older than 60 years who had their first relapse, GO as a single agent was associated with a 30% overall response rate,[127] leading to accelerated FDA approval in 2000. Other randomized phase II trials comparing GO with induction chemotherapy and chemotherapy alone confirmed these results.[128,129] However, a large phase III study evaluating the effects of GO in combination with chemotherapy versus standard induction therapy in adults younger than 60 years with newly diagnosed AML failed to show superiority of the GO arm with respect to overall efficacy, RFS, and OS and demonstrated increased induction mortality in the GO arm.[130] Based on results from this study and concerns about high frequencies of hematologic and liver toxicity, approval for GO was voluntarily withdrawn in 2010. Since then, resurrection of GO has been widely discussed, citing the exceptionally low induction mortality of 1% in the control arm of the aforementioned study and typical induction mortality of 5% in the GO arm, as well as a lower dose of daunorubicin in the GO arm, complicating direct comparison of both groups.[131] Several other large randomized trials in adults with newly diagnosed AML have shown no difference in remission rates but a significantly higher EFS and OS in patients receiving GO in conjunction with chemotherapy, with particular benefit for younger adults who have favorable cytogenetics.[132,133] Furthermore, trials using lower dose GO either at single or fractionated dosing no longer showed an increase in hepatotoxicity or veno-occlusive disease.[133] In pediatric patients, an increased incidence of veno-occlusive disease was also limited to high-dose GO, and a phase I study of GO in combination with busulfan and cyclophosphamide conditioning for 12 children with CD33+ AML showed no GO-associated dose-limiting toxicities.[134] CD33 expression in childhood AML is heterogeneous, but high CD33 expression is associated with adverse disease characteristics such as fms-related tyrosine kinase 3 internal tandem duplication (FLT3-ITD) and independently predicts poor outcome.[135] Initial phase I and compassionate use data suggested efficacy of GO monotherapy in some patients,[136,137] and subsequent studies established that combination of GO with chemotherapy was well tolerated in the pediatric population.[138,139] In a study that administered chemotherapy in combination with GO to patients with poor end-induction MRD responses, 27 of 29 patients had a reduction in MRD and 13 of 29 patients became MRD negative, including 4 of 8 patients who had MRD levels greater than 25%.[140] However, no published pediatric trials have compared GO with chemotherapy versus chemotherapy alone in a randomized fashion.

Inotuzumab ozogamicin is a calicheamicin-linked mAb directed against CD22, a marker that is highly expressed in ALL. It has been evaluated in a phase II trial for relapsed or refractory adult ALL with promising responses and in a phase I/II trial for adults with relapsed NHL, where it showed high response rates and PFS in combination with rituximab.[141] It is currently undergoing further evaluation in several adult trials. No pediatric clinical trials have been conducted thus far, although preclinical studies suggest sensitivity of pediatric B-ALL blasts to inotuzumab ozogamicin in vitro.[142]

Within the group of immunotoxins, BL22 is an antibody that is bound to a modified Pseudomonas exotoxin and directed against CD22. A phase I trial of BL22 in pediatric patients with relapsed or refractory CD22+ ALL or NHL had an acceptable safety profile but did not show any responses, leading to an ongoing phase I trial of a second-generation antibody, CAT-8015, with improved binding affinity and in vitro cytotoxicity (trial NCT00659425). BL22 has shown promise in phase II trials for the treatment of hairy cell leukemia in adults,[143] and CAT-8015 is also being investigated in a phase I trial. Neutralizing antibody responses to BL22 have been documented in some patients and present an obstacle to retreatment.

Antibodies in the Modulation of Regulatory Pathways

During a physiologic T-cell response, the balance between costimulatory and inhibitory signals (so-called immune checkpoints) is critical to allow for efficient T-cell activation while limiting the duration and amplitude of T-cell responses, thereby protecting against chronic inflammation and autoimmunity.[144] CTLA-4 and PD-1 are examples of inhibitory receptors that are upregulated by T cells during the course of an immune response and inhibit T cells upon binding to their respective ligands. In the process of immunoediting, tumor cells or nontransformed cells in the tumor microenvironment express inhibitory ligands to escape immune surveillance.[145] However, given that many of these immune checkpoints are mediated by ligand-receptor interactions, they lend themselves to therapeutic blockade with mABs. In contrast to TA-specific mABs, such mABs do not target the tumor but rather target lymphocyte receptors or their ligands to unleash intrinsic antitumor activity.

CTLA-4 was the first inhibitory receptor to be clinically targeted. CTLA-4 is upregulated on activated T cells, where it dampens T-cell activation upon engagement with the B7 (CD80/CD86) receptors on DCs. Although expressed by CD8+ T cells, its major impact is the inhibition of CD4+ helper T cells and enhancement of the activity of Tregs, which express CTLA-4 constitutively.[146] Although the exact mechanism by which CTLA-4 enhances Treg function is not known, numerous studies have documented that the ratio of effector T cells to Tregs in the tumor microenvironment plays a crucial role in the control of tumors and correlates with outcome.[147,148] After demonstration of significant tumor regressions by single-agent anti-CTLA-4 mAb in conjunction with GVAX by Leach et al.[149] and van Elsas et al.,[150] two fully humanized anti-CTLA-4 mABs, ipilimumab and tremelimumab, entered phase I clinical trials in 2000. These mABs demonstrated ~10% objective response rates in patients with refractory metastatic melanoma who received either GVAX[151] or gp100 peptide vaccines.[152] The initial phase III trial with tremelimumab plus dacarbazine compared with dacarbazine alone did not show benefit at the dose used,[153] but a later trial comparing ipilimumab plus dacarbazine versus dacarbazine plus placebo showed improved outcomes with ipilimumab.[154] After a phase III trial with ipilimumab alone or combined with a gp100 peptide vaccine versus gp100 alone, which demonstrated a survival benefit in both ipilimumab groups, ipilimumab was approved in 2011 by the FDA for use in persons with advanced melanoma.[155] Up to 30% of patients may experience severe immune-related adverse effects (the most common being colitis) with ipilimumab, which modestly correlate with response. Steroids and TNF blockade have been used in clinical management; some adverse effects such as hypophysitis may be long lasting or irreversible, although they are readily managed with hormone replacement therapy. Trials in several adult malignancies are assessing Ipilimumab alone or in combination regimens such as with chemotherapy (trials NCT01331525 and NCT01473940), in combination with GM-CSF (trial NCT 01530984), or with androgen ablation in persons with prostate cancer (trial NCT 01377389). The necessity for rigorous evaluation of novel combination regimens is highlighted by significant hepatotoxicity observed during concurrent administration of ipilimumab and the BRAF inhibitor vemurafenib.[156] In the pediatric population, a first phase I trial is underway to evaluate ipilimumab in the treatment of refractory solid tumors and lymphoma (trial NCT01445379).

The PD-1/PD-L1 axis has been another focus of clinical investigation. PD-1 is expressed by activated T cells, B cells, and NK cells. PD-1 binding to its ligands PD-L1 or PD-L2 (expressed on DCs and in peripheral tissues) inhibits kinases that are involved in T-cell activation. Furthermore, PD-1 is expressed on Tregs, where it enhances proliferation upon PD-1 engagement with its ligand.[157] Whereas CTLA-4 regulates the immune response at the time of T-cell activation in the lymphoid organs, PD-1 primarily limits the activity of T cells in peripheral tissues. PD-1 ligands are upregulated on the tumor cell surface and on myeloid cells in the tumor microenvironment of a variety of human malignancies, where they mediate immune resistance.[145,158,159] Studies in mouse models demonstrate enhanced antitumor immunity through blockade of PD-1 or its ligands, while suggesting a favorable safety profile compared with CTLA-4 based on a comparatively mild phenotype of PD-1, PD-L1, and PD-L2 knockout mice. The first phase I trial with a single-dose fully human anti–PD-1 mAb yielded promising results, including one complete response.[160] A subsequent phase I trial evaluating sequential treatment with an anti–PD-1 mAb in adults with a variety of malignancies demonstrated quite durable objective response rates of 36% in patients with PD-L1+ tumors and a safety profile comparable with or better than that of ipilimumab.[161] Investigators of a concurrent phase I trial exploring blockade of PD-L1 rather than PD-1 reported an objective response rate of 6% to 17% depending on the underlying malignancy but did not consider PD-L1 expression in the tumor.[162] Ongoing phase I/II trials are investigating blockade of PD-1/PD-L1 in various malignancies either alone (trial NCT01354431); with ipilimumab (trial NCT01024231); with a gp100, MART-1, and NY-ESO-1 peptide vaccine (trial NCT01176461); or in conjunction with chemotherapeutic agents (trial NCT01313416). Several other immune-checkpoint molecules are emerging as candidates for therapeutic blockade, such as lymphocyte-activation gene 3 (*LAG3*), 2B4, B- and T-lymphocyte attenuator (BTLA), T-cell immunoglobulin and mucin domain 3 (TIM3), A2aR, and KIR. Anti-KIR mABs aim to interfere with the interaction of inhibitory KIR receptors on NK cells and their ligands to create a missing-ligand situation and induce NK-cell–mediated tumor killing. Results from two phase I trials in adults with multiple myeloma and AML have determined safe and tolerable doses at which inhibitory KIR saturation can be achieved, and RFS in patients with AML compared favorably with that in historic control subjects.[163,164]

The stimulation of activating costimulatory pathways such as 4-1BB and inducible costimulator (ICOS) by way of therapeutic mAb administration is another strategy undergoing evaluation in early trials.[165]

ADOPTIVE CELLULAR IMMUNOTHERAPY

GVL Effect in HSCT and Donor Lymphocyte Infusions

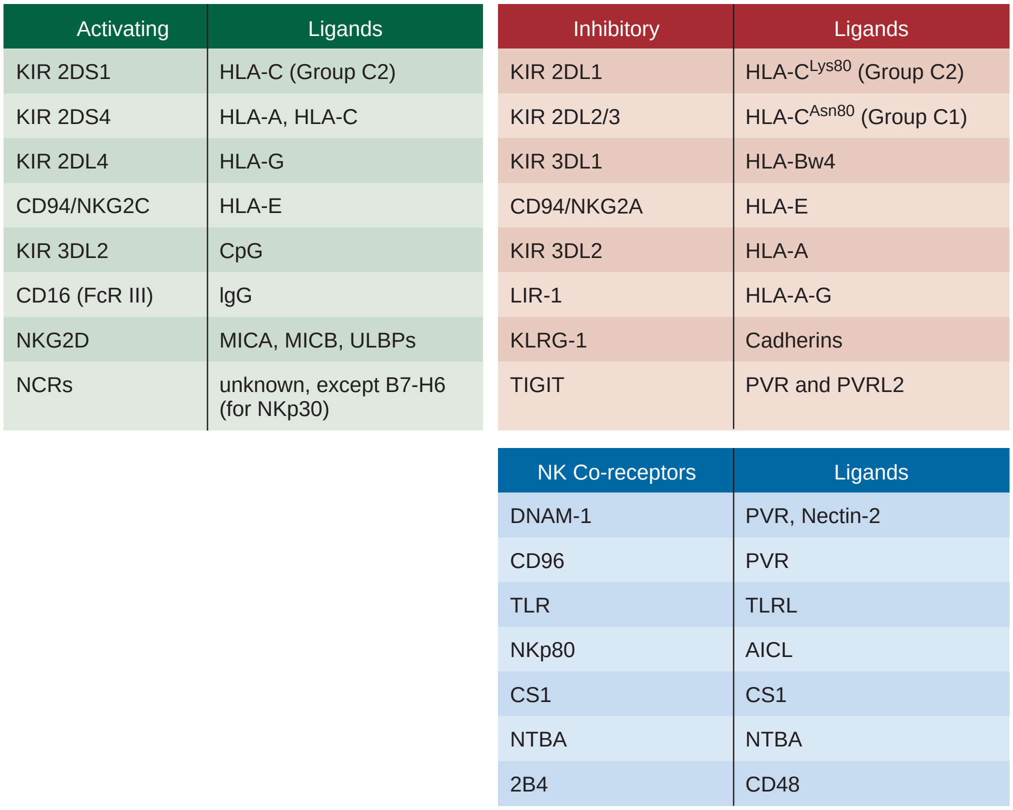
Allogeneic HSCT is a well-established curative treatment, particularly for hematologic malignancies, and immune-mediated antileukemia effects are increasingly recognized as central to its therapeutic benefit. Myeloablative preparative chemotherapy regimens with or without total body irradiation are aimed at eradicating residual tumor cells and suppressing host immunity to prevent rejection of donor HSCs. However, patients can also be cured with reduced-intensity conditioning regimens, which facilitate engraftment but may not lead to complete eradication of leukemia cells. This outcome attests to the importance of immune recognition and eradication of residual tumor cells by donor cells in a process termed GVL, which is critical for long-term cure. Evidence of the GVL effect was provided by polymerase chain reaction–based evaluation of *BCR/ABL* transcripts in 92 patients with CML, of whom 80% to 83% still had detectable *BCR/ABL* transcripts within 6 months after transplant. Six to 24 months after transplant, 80% to 88% of patients who had received a T-cell–depleted transplant remained PCR positive compared with 26% to 30% who had received unmodified marrow.[166] Although a patient's own immune cells may have been rendered tolerant to their cancer, donor cells can recognize tumor cells through expression of TAs and mHAs. Donor and recipient are maximally matched for the HLA loci on chromosome 6 to minimize GVHD, but immune recognition of mHAs encoded by genetic polymorphisms throughout the human genome can occur.[167] Initial evidence for GVL was provided by reports that recipients of syngeneic stem cells were more likely to relapse than were HLA-matched allogeneic recipients, in whom GVHD developed.[168] Subsequently a sizable body of clinical literature established that patients experiencing GVHD were less likely to relapse, that leukemia remissions could occur in association with worsening GVHD[169] and after stopping immunosuppressive GVHD prophylaxis,[170] and that T-cell depletion of grafts was associated with higher relapse rates in persons with myeloid leukemias.[171]

Kolb and colleagues.[172] first showed that DLIs could mediate a GVL effect without additional chemotherapy or radiation, and that they induced disease remissions in patients with relapsed CML after allogeneic HSCT. The use of DLI has been less effective for patients with acute leukemias after HSCT, with CR rates ranging from 5% to 18% and 15% to 29% for ALL and AML, respectively, compared with 60% to 80% for CML.[173,174] This finding can be partially explained by higher disease burden and rate of leukemic growth, but for reasons that are not well understood, myeloid leukemias overall appear more amenable to DLI. Limited data on the efficacy of DLI are available in the pediatric population, but responses have been reported in patients with pediatric AML[175] and juvenile myelomonocytic leukemia.[176] Importantly, toxicities from DLI are not trivial and include GVHD and marrow aplasia, with a treatment-related mortality rate estimated in the 12% to 22% range.[177-179] Unfortunately, the most efficient GVL responses often arise in the setting of GVHD. Therefore efforts have focused on dissecting the immunologic mechanisms of GVL and exploiting the GVL effect while preventing GVHD. Identification of tissue-restricted expression of antigens targeted by GVL versus GVHD has been key in this endeavor. As shown in a phase I trial, adoptive transfer of T cells specific for mHas is feasible, but restricted expression of the mHA on tumor or hematopoietic cells is crucial for a favorable toxicity profile.[180,181] Ongoing trials are exploring the infusion of donor lymphocytes specific for Wilms tumor–1 protein,[182,183] a transcription factor that is overexpressed in leukemias, as a directed DLI strategy (trials NCT00620633 and NCT00608166). Genomic approaches are likely to identify previously unknown mHAs that could be targeted.[184] Another area of interest concerns the role of alloreactive NK cells, which mediate a GVL effect and are intriguing because they do not cause GVHD.

Adoptive Therapies Exploiting NK-Cell Alloreactivity

NK cells are innate effector cells capable of rapid killing via degranulation and release of toxic granules in an early defense against malignant transformation. NK cells facilitate stem cell engraftment, fight infection, and control cancer, yet they do not cause GVHD. NK-cell alloreactivity is an important concept in haploidentical HSCT and allogeneic NK-cell therapies.[185] Human NK-cell activity is regulated by a complex system of inhibitory and activating receptors. One of the key regulators is the polymorphic KIR gene family. KIRs can be activating or inhibitory in nature and are named on the basis of their structure. This naming system distinguishes between the number of immunoglobulin-like domains (e.g., KIR*2D* vs. KIR*3D*), as well as *l*ong and *s*hort tails (KIR2D*L* vs. KIR2D*S*), and it numbers the different receptors within the structural group in order of discovery (KIR2DL*1* vs. KIR2DL*2*). With the exception of KIR2DL4, KIRs with long tails are generally inhibitory, whereas KIRs with short tails are activating in nature (Fig. 47-6). Three levels of KIR diversity exist: gene content, allele, and expression. A unique feature of the human KIR system is the existence of two distinctive groups of gene-content haplotypes that were identified in population studies. Group A haplotypes have a simple and constant gene content dominated by inhibitory KIRs, whereas group B haplotypes are characterized by a higher content of activating KIRs and greater gene content and variability. KIR distribution along the centromeric and telomeric motifs of the haplotype further plays a role in the ability to regulate NK-cell activity (Fig. 47-7).[186] Substantial allelic polymorphism occurs within the haplotypes, and KIR genotypic alleles are numbered analogously to HLA alleles (e.g., KIR2DL1*001 vs. KIR2DL1*002). Lastly, the expression level of each of the inherited KIR genes may vary greatly, because KIRs are clonally distributed on NK cells and individual cells express different sets of inhibitory or activating KIRs.[187] This situation illustrates why both genotyping and cell surface phenotyping are needed to accurately predict NK-cell alloreactivity between donor and recipient. Eight of the KIR family members are known to recognize MHC-I molecules, including HLA-A, HLA-B, HLA-C, and HLA-G.[188] NK cells are further regulated by a variety of other receptors, many of which recognize stress ligands that are upregulated by tissues as a signal for inflammation, infection, DNA damage, and malignant transformation (see Fig. 47-6).

An important concept of NK-cell biology is the "licensing" of NK cells. Although the exact mechanisms of licensing are yet to be fully understood, licensing provides a scientifically based concept of how NK cells maintain the balance between self-tolerance and the ability to respond to infection and malignant transformation.[189] Licensed NK cells have a matching HLA ligand for their inhibitory KIR receptor(s), which "educates" them with respect to ligand expression on healthy tissues. In steady state, ligation of the inhibitory KIR prevents them from attacking healthy tissues. However, "understanding" what normal ligand expression looks like, it renders them functional for attack in a missing ligand situation (either due to HLA class I downregulation in the tumor microenvironment or in an allogeneic setting where the recipient does not express the corresponding HLA ligand) or when tissues upregulate stress ligands that trigger activating NK-cell receptors. Unlicensed NK cells express a certain inhibitory KIR in the absence of its cognate ligand, which is possible because KIR and HLA genes are located on separate chromosomes and segregate independently. Because the ligand is lacking, unlicensed NK cells are "uneducated" and functionally are considerably less responsive in steady state.[190] However, when stress ligands are upregulated and deliver a signal to activating NK-cell receptors, unlicensed NK cells more readily mediate cytotoxicity than licensed NK cells because they do



Activating	Ligands
KIR 2DS1	HLA-C (Group C2)
KIR 2DS4	HLA-A, HLA-C
KIR 2DL4	HLA-G
CD94/NKG2C	HLA-E
KIR 3DL2	CpG
CD16 (FcR III)	IgG
NKG2D	MICA, MICB, ULBPs
NCRs	unknown, except B7-H6 (for NKp30)

Inhibitory	Ligands
KIR 2DL1	HLA-C$^{\mathrm{Lys80}}$ (Group C2)
KIR 2DL2/3	HLA-C$^{\mathrm{Asn80}}$ (Group C1)
KIR 3DL1	HLA-Bw4
CD94/NKG2A	HLA-E
KIR 3DL2	HLA-A
LIR-1	HLA-A-G
KLRG-1	Cadherins
TIGIT	PVR and PVRL2

NK Co-receptors	Ligands
DNAM-1	PVR, Nectin-2
CD96	PVR
TLR	TLRL
NKp80	AICL
CS1	CS1
NTBA	NTBA
2B4	CD48

Figure 47-6 Overview of the receptors governing natural killer-cell activity and their ligands. Natural killer *(NK)* cell surface receptors are classified based on their function as inhibitory receptors, activating receptors, or activating coreceptors. Several other receptors are involved in the regulation of NK-cell activity but are not depicted here. *AICL,* Activation-induced C-type lectin; *CD,* cluster of differentiation; *CpG,* CpG oligodeoxynucleotide; *HLA,* human leukocyte antigen; *IgG,* immunoglobulin G; *KIR,* killer cell immunoglobulin-like receptor; *KLRG-1,* killer cell lectin-like receptor subfamily G, member 1; *LIR,* inhibitory leukocyte immunoglobulin-like receptor 1; *MICA,* MHC class I–related chain A; *NCR,* natural cytotoxicity receptors; *NK,* natural killer; *NTBA,* NK-T-B antigen; *PVR,* poliovirus receptor; *TLR,* toll-like receptor; *TIGIT,* T cell immunoreceptor with Ig and ITIM domains.

not have to overcome inhibition via inhibitory KIRs (Fig. 47-8).[191]

Approximately 60% of persons have inhibitory KIRs for which they lack the cognate HLA class I ligands, and they may possess substantial numbers of unlicensed NK cells. This situation has been associated with autoimmune disease, protection from infection and cancer, and pregnancy outcome, but it may also predict the immunologic response to therapy. In an analysis of KIR-HLA immunogenetics in patients with high-risk neuroblastoma who were undergoing multimodal therapy, including autologous stem cell transplant (ASCT) and anti-GD2 mAb therapy, the presence of unlicensed NK cells was associated with significantly improved OS and reduced cumulative incidence of progression.[192] The mechanism of this benefit appeared to be due to enhanced ADCC by unlicensed NK cells during the anti-GD2 mAb therapy rather than ASCT.[193]

The importance of human NK cells in cancer surveillance was documented in an epidemiologic study by Imai and colleagues,[194] and the initial model of NK-cell alloreactivity in the HSCT setting was proposed by Valiante and Parham[195] in 1997. Ruggeri et al.[196] first reported that the KIR ligand was an important factor in determining AML relapse risk after haploidentical HSCT. These investigators demonstrated that the probability of relapse at 5 years was 0% in 20 patients with a KIR-ligand incompatible donor, compared with 75% in 37 patients with a KIR-ligand compatible donor,[196] and later consolidated similar results in a larger cohort.[197] A plethora of clinical studies have since been conducted in the sibling donor, URD, and cord blood (CB) setting with conflicting results. As succinctly reviewed by Leung,[188] several studies showed no survival benefit or even inferior survival benefit in patients transplanted with a mismatch in the KIR/KIR-ligand system. This finding may in part be related to differences in T-cell alloreactivity and the definition and use of “KIR-mismatch” models, which varies widely in different studies.[188] The ligand-ligand mismatch model is based on the “missing-self” hypothesis, in which presence of the corresponding HLA ligand prevents NK-cell alloreactivity, whereas absence of the ligand in the HSCT recipient triggers attack by the NK cell. The receptor-ligand mismatch model takes into account that a “missing-self” ligand may go unnoticed if donor NK cells do not express the cognate KIR for this ligand and thus assesses not only the HLA-ligand repertoire in the recipient but also the donor KIR genotype and phenotype. The KIR-haplotype model is based on the presence or absence of a B-KIR haplotype in the donor. Likely as

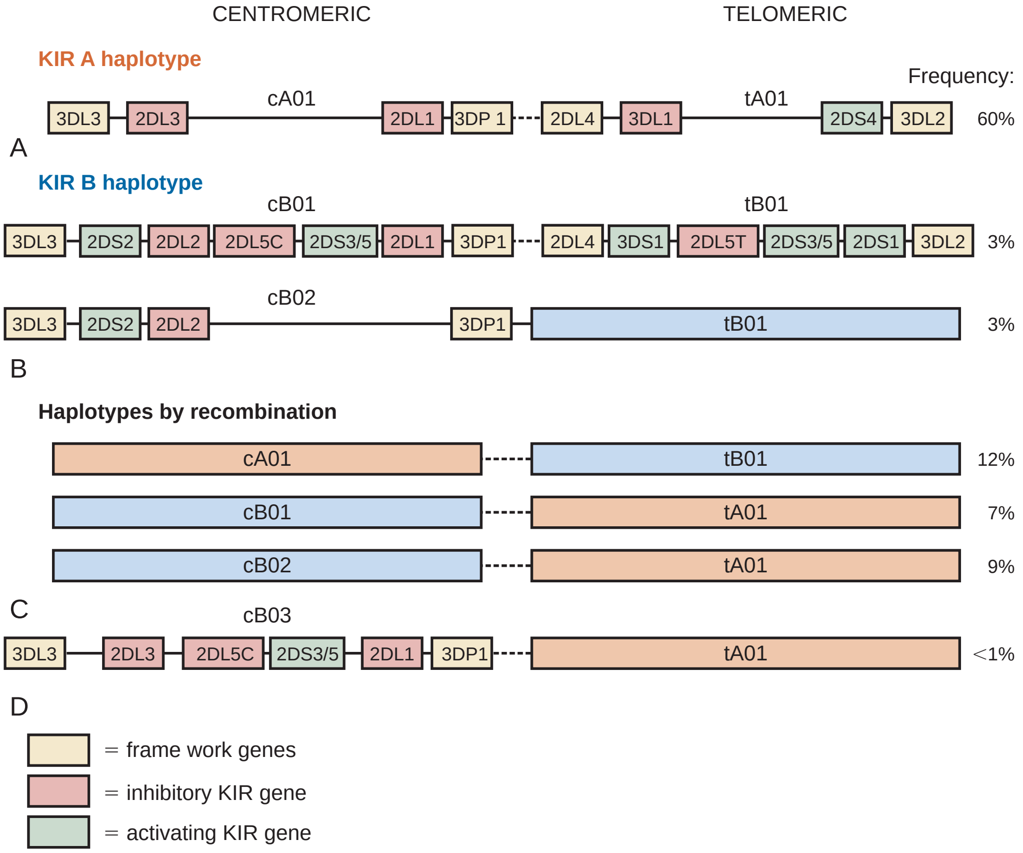


Figure 47-7 Simplified genomic map of killer cell immunoglobulin-like receptor. The human killer cell immunoglobulin-like receptor (KIR) locus maps to chromosome 19 and contains a family of highly polymorphic genes. Genetic diversity in the human KIR gene family arises from two factors: variability in KIR gene content and allelic polymorphism. Based on the combination of both, most unrelated individuals differ in KIR genotypes. A unique feature of the human KIR system is the existence of two distinctive groups of haplotypes (A and B). **A,** Approximately 60% of persons have "A" haplotype (cA01/tA01), with a simple and constant gene content, dominated by genes encoding inhibitory receptors. **B,** Group "B" haplotypes have variable and greater gene content involving genes with distinctive inhibitory receptors and a higher content of activating KIRs. The KIR haplotype model is founded on the notion that a higher number of activating KIR genes (B haplotype) in the donor increases the potential for alloreactivity and prevents relapse. **C,** Through recombination of a centromeric and telomeric cluster, various other haplotypes with "B" content have evolved, and their relative frequencies in a reference population are indicated. **D,** cB03 is an unusual B haplotype that has only been found in individuals of African descent. It contains all "A" haplotype genes but also a "B" fragment. *(Modified from Leung W: Use of NK cell activity in cure by transplant.* Br J Haematol *155:14–29, 2011.)*

a result of the fact that the B haplotype carries more activating genes than does the A haplotype, it was shown that transplants from donors with the B haplotype (and specifically centromeric motifs) reduced the risk of leukemia relapse (Fig. 47-9).[198-200]

Given that ligand-ligand mismatch always equates to the presence of a major HLA class I mismatch at the antigen level, it is not surprising that such mismatch leads to significant T-cell alloreactivity and poor survival unless it is minimized by T-cell depletion (which is standard in haploidentical SCT) or in single-unit cord blood transplantation (CBT), where up to two HLA class I mismatches are acceptable and GVHD is generally lower. Presence of T cells in the graft also alters NK-cell reconstitution, leading to lower KIR expression.[201] Differences in T-cell depletion, conditioning regimens, the source and number of stem cells, the type of GVHD prophylaxis, and the clinical status of the patient population may further explain the discrepancies between different studies. Additional factors add to the complexity of the system: Activating KIRs and specifically KIR2DS1 play a substantial role in mediating alloreactivity,[202] and in adults with AML undergoing URD HSCT, those with donors who were positive for KIR2DS1 had lower rates of relapse.[203] Killing of target cells also depends on the density of KIR-independent activating receptors on NK cells and the expression of their ligands on malignant cells. Lastly, haploidentical grafts from the mother rather than the father have been shown to confer a survival advantage, whereas donor sex did not matter in haploidentical sibling HSCT.[204] Careful consideration of all factors and a more unified approach toward prospective donor selection is poised to shed light on this complicated and fascinating field. Donor selection may include consideration of the degree of receptor-ligand KIR mismatch, origin from the mother versus father, B-haplotype content, expression of specific donor-activating KIRs such as KIR2DS1, size of the alloreactive donor NK-cell pool, and in vitro cytolytic activity.

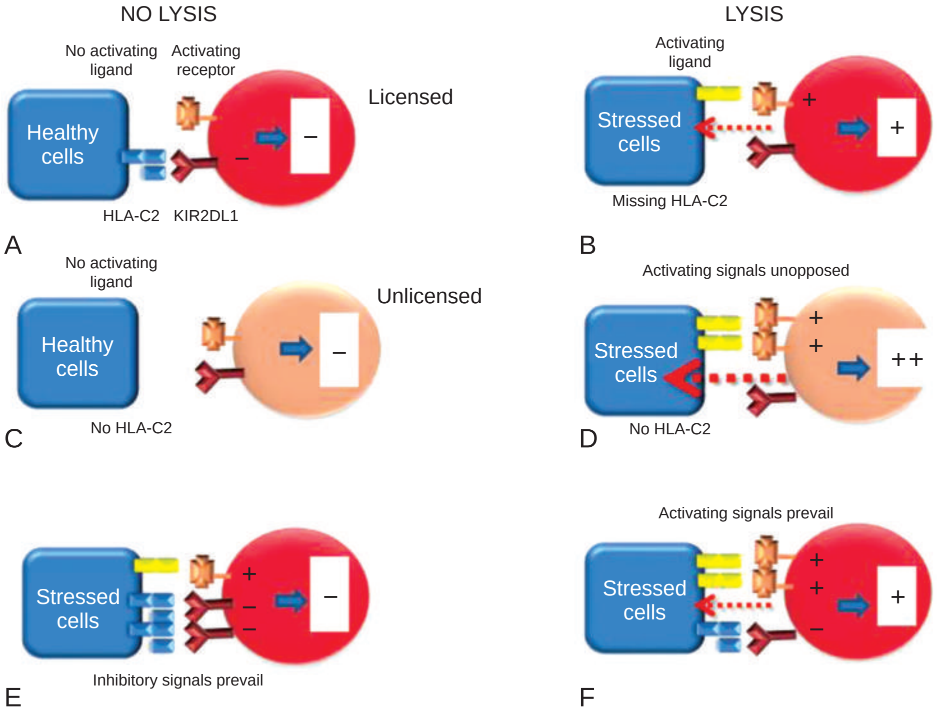

Figure 47-8 Natural killer cell reactivity is regulated by the balance of inhibitory and activating natural killer cell receptors. **A,** The presence of the appropriate ligand for an inhibitory killer cell immunoglobulin-like receptor (KIR) in an individual "licenses" the natural killer (NK) cell but delivers an inhibitory signal to the cell. **B,** If the cognate ligand is downregulated (such as in the tumor microenvironment of the same individual) or absent (in a ligand-negative allogeneic recipient), but activating ligands are expressed, NK-cell mediated killing takes place. **C,** Because of independent segregation of human leukocyte antigen (HLA; chromosome 6) and KIR (chromosome 19), an individual may lack the cognate ligand for its inhibitory receptor (autologous KIR-HLA mismatch). This scenario results in unlicensed NK cells that are hyporesponsive at baseline. **D,** However, in the presence of activating ligands, unlicensed NK cells are able to mediate killing much more readily than licensed NK cells because they do not have to overcome inhibitory signals. **E,** In contrast, licensed NK cells have to overcome inhibitory signals and will only mediate killing if activating signals prevail (**F**).

NK-cell alloreactivity is actively explored in pediatric trials by various strategies. Haploidentical HSCT involves a myeloablative or reduced-intensity conditioning regimen followed by a T-cell–depleted hematopoietic stem cell (HSC) graft from a haploidentical donor. Advantages of this approach include optimization of NK-cell alloreactive effects, immediate donor availability if no matched sibling is identified, and availability of the donor for post-transplant cellular therapies. With advances in graft manipulation and cell dose, increasingly promising results have been reported in children with malignant and benign hematologic disorders[205-208] and have led to its exploration as a treatment strategy for refractory solid tumors.[209] Novel approaches, such as use of αβ-TCR negative selection aimed at facilitating rapid engraftment and immunity by maintaining NK cells and γδ–T cells in the graft are currently being tested (trial NCT01810120). Haploidentical NK-cell transplantation as a consolidation strategy in pediatric AML (trial NCT00187096) and in relapsed or refractory neuroblastoma (trial NCT00698009) is to be distinguished by administration of a nonmyeloablative immunosuppressive regimen followed by haploidentical KIR-mismatched NK-cell infusion devoid of HSCs.[210] Yet another approach is the infusion of haploidentical KIR-mismatched NK cells without a preparative regimen after ASCT for hematologic malignancies in an effort to minimize relapse risk (trial NCT00660166).

Adoptive Therapy Using Cytokine-Induced Killer Cells

Cytokine-induced killer cells (CIKs) are ex vivo–activated cytotoxic lymphocytes characterized by a CD3+ CD56+ phenotype, acquisition of NK-cell properties, and marked upregulation of NKG2D. They can be generated from bone marrow, CB, or peripheral blood mononuclear cells by sequential addition of IFN-γ, OKT-3 (an anti-CD3 agonistic antibody), and IL-2 or IL-15.[211] Although CIKs are capable of specific MHC-restricted recognition, they can lyse a broad array of tumor targets in a non–MHC-restricted, NKG2D-dependent fashion without displaying significant alloreactive potential that could lead to GVHD.[212] Clinical experience with CIKs is still limited. Several small phase I trials demonstrated feasibility and a relatively low incidence of GVHD when donor-derived CIKs were administered to relapsed patients after allogeneic HSCT, although modest clinical benefit was limited to a few patients.[213-215] A study of CIKs in the

Figure 47-9 Natural killer cell alloreactivity. **A,** If donor and recipient have matching killer cell immunoglobulin-like receptor *(KIR)* ligands (C2/C2), no natural killer (NK) cell alloreactivity is expected. **B,** If the donor has a KIR ligand (C2) that is absent in the recipient (no C2; recipient has C1), lysis of recipient cells occurs, which is the basis for the ligand-ligand mismatch model. **C,** However, depending on the donor's KIR genotype and/or phenotype, the KIR for the recipient's "missing ligand" may have no or very low expression on donor NK cells. In such event, the absence of C2 in the recipient may not be noticed. This scenario forms the basis of the receptor-ligand model, which considers KIR receptors on the donor's NK cells and KIR ligands on the recipient cells, rather than respective ligands alone. **D,** Example of a scenario with optimal donor NK-cell reactivity: The donor has a strong inhibitory KIR allele (KIR2DL2) and the NK cell is licensed by recognition of KIR2DL2's cognate ligand C1 in the donor. C1 is absent in the recipient, and this missing-ligand situation is recognized by the licensed NK cell. The donor carries a B haplotype containing the strong activating KIR2DS1. KIR2DS1 may also activate the NK cell by engaging its ligand C2 on the recipient leukemia cells.

treatment of relapsed adult HL and NHL after ASCT demonstrated partial responses in select patients.[216] Pediatric patients with relapsed AML or sarcomas after haploidentical HSCT have also been reported to have received CIKs safely, but with limited efficacy in these heavily pretreated patients.[211] Novel preclinical approaches that may improve efficacy include introduction of CARs into CIKs as a mode of redirection against surface markers such as CD33 and CD123 for the treatment of AML.[217]

Adoptive T-Cell Therapy

The potential therapeutic role of lymphocytes was first revealed by studies of melanoma showing that the isolation, expansion, and adoptive transfer of TILs back into the patient[218] could result in significant clinical response rates.[219,220] Adoptive transfer of autologous TILs also showed promise in pilot clinical trials for ovarian cancer.[221,222] However, the isolation of TILs is labor intensive and technically difficult, and TILs cannot be obtained in all patients. Morgan et al.[222] developed a strategy to overcome this problem by cloning the α and β chains of a TCR recognizing the MART-1 TA from a patient with metastatic melanoma who demonstrated near-complete regression after adoptive transfer of TILs. This strategy permitted adoptive T-cell therapy of HLA-matched patients with melanoma after their autologous T cells had been engineered to express the anti-MART1 TCR via retroviral gene transfer. With this method, select patients who sustained high levels of circulating engineered T cells achieved objective regressions of metastatic melanoma lesions.[223] However, this approach involved MHC-restricted recognition of the TA, thereby limiting availability to HLA-matched patients and remaining vulnerable to MHC downregulation in the tumor microenvironment.

CARs have since emerged as a powerful alternative tool to redirect the specificity and function of T cells and other immune cells. Gross and colleagues[224,225] pioneered the generation of TA-specific T cells by genetically modifying non–tumor-reactive T cells to express a CAR that specifically binds to TA in an MHC-unrestricted manner. CARs are hybrid receptors consisting of a single-chain variable fragment (scFv) antibody or another extracellular domain recognizing the TA of interest linked to intracellular signaling modules that mediate T-cell activation upon ligation of the CAR's extracellular domain (Fig. 47-10, *A*). Gene transfer of the CAR into T cells

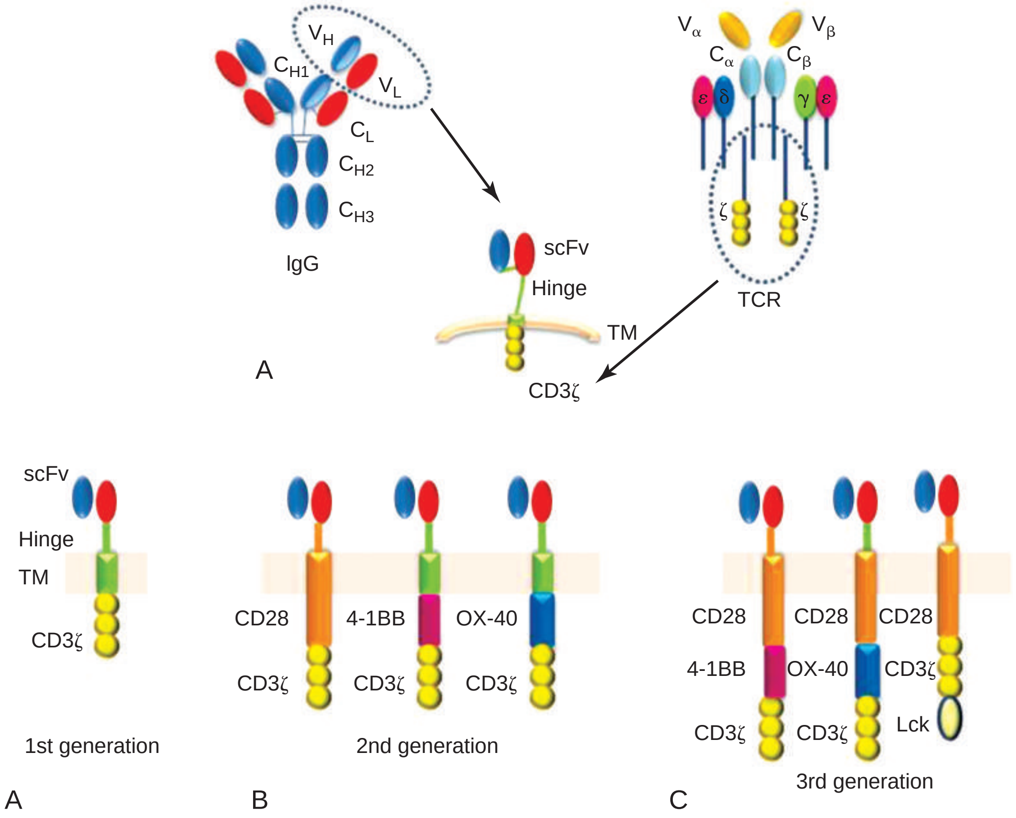

Figure 47-10 Chimeric antigen-receptor T-cells. **A,** T cells can be transduced to express chimeric antigen-receptor cells (CARs) that endow them with specificity to a particular tumor antigen (TA; signal 1), regardless of their cognate T-cell receptor *(TCR)*. Although many other iterations have been developed, the CAR commonly consists of the single-chain variable fragment *(scFv)* derived from a monoclonal antibody against a TA that is linked to an immunoreceptor tyrosine activation motif such as the CD3ζ chain. **B,** Second-generation CARs also include a costimulatory signaling domain (signal 2) in the same CAR to improve T-cell activation, expansion, and persistence. **C,** Third-generation CARs include two costimulatory signaling domains (to enhance signal 2), although it is not clear whether this is beneficial. *IgG,* Immunoglobulin G; *TM,* transmembrane region. *(Modified from Baumeister SH, Dranoff G: Principles of targeted immunotherapy. Translational cancer research: molecular therapeutics. In Kurzrock R, editor:* Targeted therapy in cancer, *Wiley Publications, Hoboken, N.J., in press.)*

can be achieved with use of γ-retroviral vectors, lentiviral vectors, or electroporation.[226] The transduced T cell acquires specificity for the targeted TA while retaining its endogenous TCR and can be endowed with supraphysiologic properties to carry out immediate and long-term effector functions. The ability to recognize TAs in HLA-independent fashion allows CARTs to attack tumor cells in the tumor microenvironment, where MHC downregulation is a major immune evasion mechanism. Furthermore, a single CAR construct can be used for the transduction of patient T cells regardless of HLA type and allows for large-scale production of the viral vector for clinical use. However, CARTs still have to be manufactured individually, either from a patient's autologous T cells or from matched allogeneic donor-derived T cells after HSCT. In contrast to native TCRs, which cannot recognize certain targets such as glycolipids, CARTs can be targeted to any cell surface antigen to which an mAb can be generated. Humanized scFvs have been developed from murine mABs[227] and are preferentially used to avoid CART elimination by way of an immune response against the murine antibody fraction.[228] With emerging clinical experience and scientific insights, CAR design has become considerably more sophisticated and continues to evolve. First-generation CARs typically consist of an extracellular binding moiety such as the scFv of an mAb, linked via a hinge and transmembrane region to an intracellular immunoreceptor tyrosine activation motif such as the CD3ζ-chain or, less commonly, the FcεRIγ (see Fig. 47-10, *A*). Such CARs deliver "signal 1," resulting in modest T-cell activation, target cell lysis, IL-2 secretion, and in vivo antitumor function (Fig. 47-11, *A*). However, a costimulatory "signal 2" is required for full T-cell activation, and the lack thereof may result in T-cell anergy. To mimic physiologic T-cell activation, second-generation CARs were designed to include a costimulatory domain such as CD28, ICOS, or TNF receptor family members (e.g., 4-1BB or OX40; Fig. 47-10, *B*). Third-generation CARs include two or more costimulatory domains but may not necessarily be superior (Fig. 47-10, *C*). Costimulatory support can be provided to CARTs by different approaches. Frequently, the costimulatory

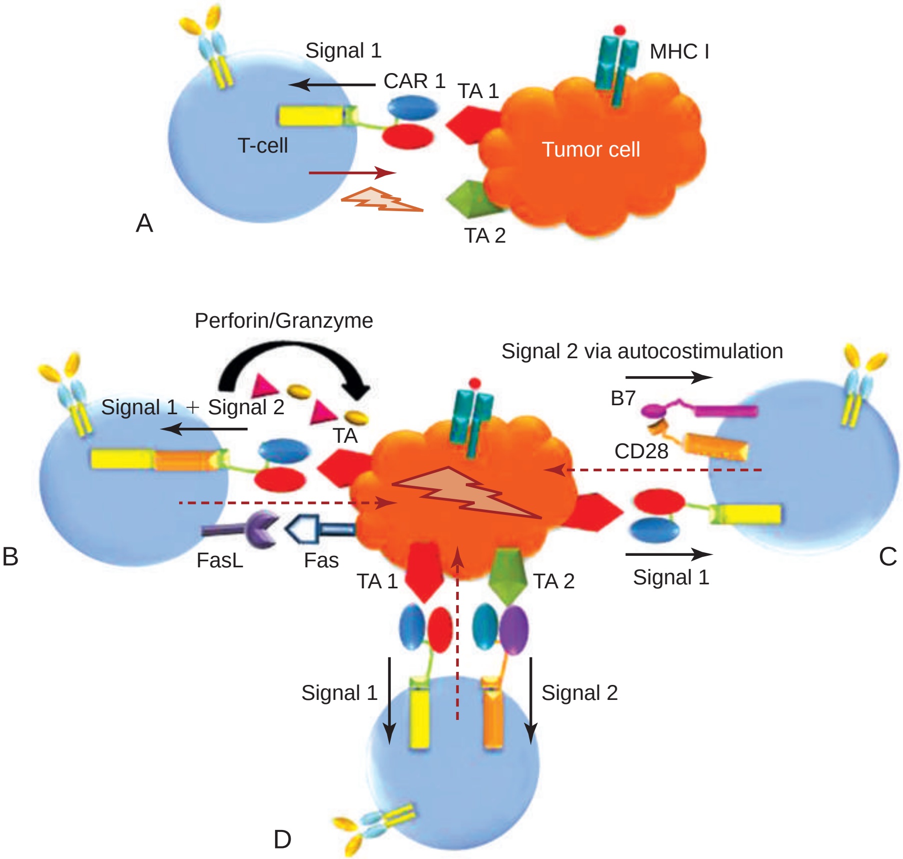

Figure 47-11 Tumor-cell elimination by chimeric antigen-receptor T cells. **A,** T cells expressing the chimeric antigen receptor (CAR) construct retain their cognate T-cell receptor but are newly endowed with specificity for the tumor antigen *(TA)*. CAR T cells can recognize the TA in major histocompatibility complex *(MHC)*–unrestricted fashion and become activated upon binding to the TA. In the absence of costimulatory signals, first-generation CARs are unable to achieve full antitumor potential and have demonstrated poor persistence in clinical phase I studies. Therefore different strategies to provide costimulatory support to CARTs were developed and significantly enhance CART-mediated killing of tumor cells and CART persistence in the patient. **B,** Costimulatory signaling domains can be embedded into the CAR construct. **C,** T cells can be engineered to express the ligand(s) for their costimulatory receptor(s) independent of the CAR, facilitating auto-costimulation. **D,** A transsignaling strategy whereby the T-cell activation signal and costimulatory signal are dissociated in two CARs with differing TA specificity not only provides a costimulatory signal but can also minimize toxicity against healthy tissues expressing one but not both of the TAs, because full CART activation is dependent on recognition of both TAs. *(Modified from Baumeister SH, Dranoff G: Principles of targeted immunotherapy. Translational cancer research: molecular therapeutics. In Kurzrock R, editor:* Targeted therapy in cancer, *Wiley Publications, Hoboken, N.J., in press.)*

domain is directly embedded into the CAR (Fig. 47-11, *B*). Alternatively, the CART can be transduced to express the ligand(s) for its costimulatory receptor(s) to enable auto-costimulation (Fig. 47-11, *C*).[229] A sophisticated strategy that also improves safety by rendering T cells specific for a tumor in the absence of a tumor-restricted antigen involves combinatorial antigen recognition and balanced, dissociated signaling; T cells are transduced both with a first-generation CAR that provides suboptimal activation upon binding of one TA and a chimeric costimulatory receptor recognizing a second TA. In this scenario, full T-cell activation is only achieved if both CARs bind to their respective antigen and tissues expressing only one of the TAs are spared from CART attack (Fig. 47-11, *D*).[230] The optimal number and configuration of costimulatory signals within a CART may vary depending on the clinical scenario and is the subject of ongoing investigation. Unifying features of second-generation CARs include enhanced cytokine production, expression of antiapoptotic proteins in resting T cells, and proliferation in response to antigen when compared with first-generation CARs.[231-236] Compared with CARs that contain TNF receptor, CD28 costimulation leads to higher levels of IL-2 and IFN-γ secretion.[237] However, IL-2 can lead to Treg-mediated CART suppression,[238] and lower cytokine levels may be beneficial because they carry a reduced risk for cytokine release syndrome and may lead to sustained clinical activity. 4-1BB appeared superior in a xenograft model of ALL, but in a mesothelioma tumor model, CD28 and 4-1BB containing CARs were equivalent.[237,239] Stringent comparative studies to identify optimal CAR design would be prudent but are complicated by other variables such as use of different scFvs, the nature and length of extracellular spacer moieties,[240] methods of transduction, tumor models, and culture conditions.

CARs against a broad range of targets have been developed, and the identification of novel targets is ongoing. Early proof-of-principle trials were directed against carbonic-anhydrase-IX for the treatment of renal cell carcinoma,[241] folate receptor for metastatic ovarian cancer,[242] CD171 for neuroblastoma,[243] and CD20 for NHL.[244] Although these trials had a reasonable toxicity profile, T-cell persistence and efficacy were poor. Increasing evidence indicates that the degree of expansion and persistence of CARTs correlates with clinical efficacy but may also increase associated toxicity.[245,246] In an effort to improve persistence through ongoing antigenic TCR stimulation and to avoid theoretic off-target toxicity against unknown antigens via the endogenous TCR, the concept of selectively transducing EBV+ or cytomegalovirus (CMV)+ T cells has been explored. An anti-GD2-CAR trial in children with neuroblastoma utilized this approach by coinfusing EBV-specific and polyclonal anti-GD2-CARTs. Although this trial showed encouraging clinical results in several patients, CART persistence was concordant with the percentage of CD4+ T cells and central memory T cells, rather than EBV+ CARTs.[245] Consideration of the phenotypic and functional heterogeneity of the T-cell pool is key because naive T cells, effector T cells, effector memory T cells, and central memory T cells differ substantially in their readiness to deliver effector function, proliferate, and persist.[247] Depending on the therapeutic goal of achieving rapid effector function versus long-term persistence, certain T-cell subtypes may be preferentially selected for CART therapy. Furthermore, some studies identified an inverse correlation between disease burden and persistence of CARTs, suggesting that conditioning chemotherapy may be beneficial.[243,248]

Many adult and ongoing pediatric CART clinical trials have focused on CD19, which is expressed by B-cell malignancies and healthy B cells but is absent on hematopoietic stem cells, early B-precursor cells, and other tissues. Undesired on-target toxicity is thus limited to B-cell aplasia. Although transient B-cell aplasia can be supported with immunoglobulin replacement, opportunistic infections are of concern, especially if CARTs and associated B-cell aplasia might persist over the life span of a young patient. Several phase I/II clinical trials have evaluated the safety and efficacy of CD19 CARs in patients with CLL, ALL, and NHL. Although the CD19-CAR constructs used in the respective trials differ in the scFvs against CD19, the type of costimulatory domain(s) used, and lentiviral versus γ-retroviral transduction regimens, the therapeutic promise of CD19 CARTs has been demonstrated by several groups.[248,249] Brentjens et al.[250] demonstrated induction of molecular remissions with a CD19-28-ζ-CAR in five adults with MRD+ ALL. Porter et al.[246] reported on three patients with CLL who were treated with chemotherapy followed by infusion of a CD19-4-1BB-ζ-CAR, whereby two patients achieved a CR and one patient achieved a partial remission. Whereas in vivo persistence of CARTs beyond a few weeks was problematic in many of the early CART trials, this group demonstrated not only persistence of CARTs in the blood and bone marrow exceeding 6 months, but also in vivo expansion of infused CARTs by greater than three log steps. Although multiple pediatric centers are now conducting CD19-CAR trials, Grupp et al.[251] reported first results utilizing a CD19-4-1BB-ζ-CAR construct in two pediatric patients with refractory pre–B-cell ALL who had experienced multiple relapses. Both patients achieved CRs, with one ongoing at 11 months after treatment. The second patient experienced a relapse 2 months after therapy with emergence of a CD19-negative escape variant. Similar to the adult trial, significant CART expansion and persistence occurred. Additionally, CARTs were detected in the cerebrospinal fluid. However, the remarkable therapeutic potential of CD19 CARTs is also associated with considerable toxicity. Adult and pediatric patients have been described as developing variable degrees of a febrile, potentially life-threatening cytokine-release syndrome that has been managed with Etanercept (a TNF-α blockade) and most effectively by Tocilizumab (an IL-6R blockade).[251] Transient neurologic toxicities such as mental status changes have also been observed and could be related to the presence of CD19 CARTs in the cerebrospinal fluid. In addition to CD19 CARTs, several pediatric trials are underway to evaluate CARTs directed against CD30+ lymphomas (trialsNCT01316146 and NCT01192464), Her2+ malignancies including osteosarcoma and glioblastoma multiforme (trials NCT00902044 and NCT 01109095), and GD2 in neuroblastoma (trials NCT00085930 and NCT01822652). As CARTs against new targets such as CD22+ B-precursor ALL[252] enter clinical trials, they may provide tools to prevent or treat CD19-negative escape variants. Allogeneic CART therapy after stem cell transplantation is another area of active investigation (trials NCT01087294 and NCT01475058).

From a safety perspective, one adverse event was reported for an adult with metastatic colon cancer who received a large dose of third-generation Her2-28-4-1BB-ζ-CARTs and developed an acute respiratory distress syndrome–like clinical picture followed by multiorgan failure, likely as a result of low level Her2 expression in healthy lung tissue.[253] A patient with CLL who was treated with CD19-28-ζ-CARTs after chemotherapy died within days of the T-cell infusion, but this death was ultimately attributed to an infectious cause.[254] To date, CARTs have otherwise been infused safely and with manageable and largely transient toxicity profiles. However, the relative toxicity or safety of a given target may only be evident when CARTs represent a significant amount of circulating lymphocytes, and trials with poor T-cell expansion may not be conclusive in this regard. Several strategies are being investigated to improve the safety and specificity of CARTs. These strategies include the integration of inducible suicide genes such as herpes simplex virus thymidine kinase (HSV-tk) or iCaspase-9 that can be pharmacologically activated and have been explored in the context of GVHD,[255-257] pharmacologically activated riboswitches that can regulate CAR expression and T-cell proliferation,[258] and inclusion of extracellular moieties such as human EGFR, which could allow targeted destruction via anti–human EGFR mAbs.[259] Contrary to gene transfer into HSCs, transduction of differentiated T cells has not been associated with insertional mutagenesis or leukemogenesis. More than 540 patient-years of follow-up from three clinical trials evaluating a CD4-ζ-CAR for human immunodeficiency virus infection showed no evidence of persistent clonal expansion or enrichment for integration sites near genes implicated in growth control or transformation.[260]

Several interesting CAR constructs have been explored in preclinical models and hold promise for clinical application. Examples include a NKG2D-receptor-CAR targeting the natural ligands of NKG2D that are overexpressed on a multitude of tumors,[261] a CAR directed against vascular endothelial growth factor receptor 2,[262] IL-12 secreting CARTs,[263] and an anti–fluorescein isothiocyanate CAR that could be used more universally to eradicate cells marked by a fluorescein isothiocyanate–labeled antibody against various TAs.[264] Other strategies of interest include expression of chemokine receptors such as CXCR2 and CCR4 to enhance trafficking of CARTs to the site(s) of tumor[265,266] and coupling of negative T-cell regulators such as PD-1 to an activating intracellular signal, allowing the T cell to prevail over PD-L1 signals in the tumor microenvironment.[267]

CAR technology is poised to include new targets and optimize extracellular binding moieties, costimulatory domain constellations, selection of T-cell subsets, transduction regimens, safety mechanisms, and other variables. The growing body of clinical experiences should further aid in the optimal incorporation of CART therapy into existing treatment regimens and inform the prevention and management of clinical toxicities.

Allogeneic Adoptive T-Cell Therapy for the Control of Viral Infections after HSCT

Viral infections after HSCT are among the most common causes of death as a result of prolonged and profound immunosuppression of the host. This scenario is especially true after CBT or in T-cell–depleted grafts, where the graft does not contain appreciable numbers of virus-experienced T cells to confer protection. Pharmacologic therapy is available but differs in efficacy depending on the virus and may not be sufficient to eradicate infection in the absence of an intact immune system. Walter et al.[268] first established in 1995 that transfer of CMV-specific CD8+ T-cell clones derived from donor bone marrow safely and effectively boosted cellular immunity against CMV after allogeneic HSCT, whereas virus-specific CD4+ helper cells are required for persistence of the transferred CD8+ CTLs. This approach was subsequently expanded to the treatment of EBV, EBV-associated PTLD, and adenovirus and further evolved toward the generation of multivirus-specific CTLs.[269-271] However, the laborious manufacturing procedure and necessary availability of the donor with respective viral immunity presented significant challenges for a broader implementation. To overcome this barrier, third-party virus-specific CTLs were introduced.[272] Establishment of a cell bank with virus-specific lines from third-party persons possessing common HLA polymorphisms and immunity to EBV, CMV, or adenovirus permitted off-the-shelf use of these CTLs. In vitro studies predicted a high degree of alloreactivity mediated by HLA-mismatched virus-specific CTLs; however, a recent multicenter study in which 50 patients with severe, refractory viral infections after HSCT received banked third-party virus-specific CTLs reported a low incidence of de-novo GVHD in two patients with a cumulative rate of complete or partial responses of 74% in the entire group.[273]

Mesenchymal Stem Cells

Multipotent mesenchymal stem cells (MSCs) are characterized by their capacity to give rise to colony-forming–unit fibroblasts and to differentiate into tissues of mesenchymal origin in vivo and in vitro. They were first isolated from bone marrow and later from other tissues such as adipose tissue and umbilical CB. Their phenotypic definition requires expression of CD73, CD90, and CD105 in the absence of CD11b, CD14, CD34, CD45, CD19, CD79a, and HLA-DR. MSC interactions with the immune system are complex, but MSCs support hematopoiesis and co-localize with HSCs during ontogeny.[274] These characteristics generated interest in using MSCs for the prevention of graft failure and promotion of hematopoietic recovery after HSCT.[275,276] A role for MSCs in bone marrow failure syndromes has also been suggested.[277] A pediatric trial of 13 patients who received parental-derived MSC coinfusions at the time of their CBTs failed to demonstrate improved hematologic recovery or reduction in rejection, but a significantly lower risk of grade 3/4 acute GVHD was observed in the patients treated with MSC compared with historic control subjects.[278] Based on their non–HLA-restricted immunoregulatory and regenerative properties, MSCs are now being actively explored as a cellular therapy for GVHD and autoimmune/inflammatory conditions. MSCs in vivo are rare, and although they can easily be obtained by simple bone marrow aspiration, they require in vitro expansion to obtain sufficient numbers. In a multicenter phase II trial, 55 patients who had severe acute GVHD refractory to first-line steroid therapy were treated with one or more infusions of non–HLA-matched bone marrow–derived MSCs. This study reported no acute or long-term adverse effects and demonstrated 30 complete and 9 partial responses. It included 25 pediatric patients, of whom 17 achieved a complete response and four achieved a partial best response.[279] A subsequent multicenter compassionate use study evaluated a premanufactured, universal donor formulation of MSCs in 12 children who had treatment-resistant grade 3/4 acute GVHD and demonstrated an overall complete response in 58%, a partial response in 17%, and a mixed response in 25%. MSC treatment was most efficacious for GI acute GVHD, with resolution of GI symptoms in 75% of patients; however, two patients experienced recurrence of GVHD with only a partial response to retreatment.[280] Adult studies have reported a mixture of complete responses, partial responses, and nonresponses in the use of MSCs for the treatment of chronic GVHD.[281] Thus far, limited studies of MSCs in pediatric patients appear to have a very favorable toxicity profile and may offer a therapeutic option for patients with treatment-refractory GVHD.

IMMUNE RESPONSE CRITERIA

An important element of cancer immunotherapy is the accurate assessment of clinical efficacy. As has been reviewed in this chapter, immunotherapy promotes the interaction between tumor and immune cells and triggers inflammatory reactions, which often correspond with an increase in tumor size during the early phases of treatment. The Response Evaluation Criteria in Solid Tumors (RECIST) or modified World Health Organization criteria that have been used to assess chemotherapy-induced solid tumor regression may therefore not provide an adequate assessment in the context of immunotherapy. In fact, false-negative interpretation as progression could preclude the most promising immunotherapy regimens. A randomized phase III trial of ipilumimab in persons with stage IV melanoma, which showed a twofold improved OS for recipients of anti-CTLA-4 mAb, most clearly illustrated that lesions might initially increase in size, and that immunotherapy responses develop more slowly than do chemotherapy responses, reflecting the gradual buildup of a lasting immune response.[155] Clearly a need exists to develop validated biomarkers to monitor the development of an immune response after therapy and identify those that best correlate with and predict clinical efficacy.[282] Careful immune analysis will also provide further mechanistic insights and translate into improved regimens. Collaborative efforts to standardize laboratory protocols for biomarkers and to implement new immune-related response criteria are underway[283,284] and will undoubtedly benefit pediatric patients as well.

CONCLUSION AND FUTURE DIRECTIONS

Critical advances have been made in appreciating the complexity of tumor immunology and dissecting the regulatory and effector components of immunity in the tumor microenvironment and beyond. As a result, a multitude of strategies capitalizing on the immune system's ability to control cancer have emerged, both with experimental therapies and increasingly with approved clinical therapies. Ongoing preclinical discoveries and important insights from clinical trials critically inform the development of novel and optimized therapies. Although some immunotherapeutic agents have shown impressive efficacy, the overall median survival advantage may not always be overwhelming. This outcome is not surprising because phase I, II, and III studies are often performed in patients with progressive disease for whom all established therapies have failed, and the studies often use immunotherapy alone. Success in cancer therapy in general has only been achieved by using multiagent or multimodality treatments, which is likely to be the case with cancer immunotherapy as well. Immunotherapy may be most beneficial when used in upfront therapeutic regimens or in MRD states, where it can aid in the complete eradication of tumor cells and prevent relapse by establishing immunologic memory. Although lymphodepleting chemotherapeutic regimens may be important to create "space" for cellular therapies, tumor vaccines or antibody-based strategies rely on a functional immune system to carry out effector functions, and such capacity may be affected in heavily pretreated patients. Several studies suggest that the immune system has the ability to increase the efficacy of existing therapeutic modalities in cancer, and the prospect of a synergistic effect of immunotherapy is highly encouraging. Although small molecule kinase inhibitors can effectuate impressive tumor responses, these drugs are frequently limited by the emergence of drug resistance. The full effect of immunotherapy is not immediate, but once developed, it can offer a sustained response that is unparalleled by other therapeutic modalities. Tumor-specific memory T cells or persistence of infused cellular products can offer long-term control, whereas other therapies are short-lived. Upon successful initiation of antitumor immunity, the immune response can be broad and reach beyond the initially targeted antigen, thus minimizing escape mutations. The combination of targeted molecular therapy with targeted immunotherapy may thus prove to be particularly efficacious and well tolerated.[285] In pediatric oncology, effective immunotherapeutic combination regimens hold particular promise for improving survival and quality of life by sparing patients from treatment with chemotherapeutic and radiotherapeutic agents that have long-term toxicity and the propensity for secondary malignancies.

Topp MS, Kufer P, Gokbuget N, et al: Targeted therapy with the T-cell-engaging antibody blinatumomab of chemotherapy-refractory minimal residual disease in B-lineage acute lymphoblastic leukemia patients results in high response rate and prolonged leukemia-free survival. *J Clin Oncol* 29:2493–2498, 2011.

A report of encouraging clinical results in adult acute lymphoblastic leukemia with a bispecfic antibody that simultaneously engages CD19 and CD3, thereby targeting T cells to the leukemia cells.

114. Younes A, Bartlett NL, Leonard JP, et al: Brentuximab vedotin (SGN-35) for relapsed CD30-positive lymphomas. *N Engl J Med* 363:1812–1821, 2010.

A report of the promising results with brentuximab vedotin in Hodgkin lymphoma and anaplastic large-cell lymphoma, which ultimately led to Food and Drug Administration approval of the drug in 2011.

131. Rowe JM, Lowenberg B: Gemtuzumab ozogamicin in acute myeloid leukemia: a remarkable saga about an active drug. *Blood* 121:4838–4841, 2013.

A summary of the clinical experience with the anti-CD33 immunoconjugate gemtuzumab ozogamicin, which was approved by the Food and Drug Administration and later withdrawn, and discussion of the rationale for considering reapproval of the drug.

144. Pardoll DM: The blockade of immune checkpoints in cancer immunotherapy. *Nat Rev Cancer* 12:252–264, 2012.

This article provides an in-depth review of various immune regulatory pathways and their therapeutic blockade.

155. Hodi FS, O'Day SJ, McDermott DF, et al: Improved survival with ipilimumab in patients with metastatic melanoma. *N Engl J Med* 363:711–723, 2010.

A report of the phase III trial that demonstrated survival advantage conferred by the anti-CTLA-4 antibody ipilimumab and led to its approval by the Food and Drug Administration for metastatic melanoma.

161. Topalian SL, Hodi FS, Brahmer JR, et al: Safety, activity, and immune correlates of anti-PD-1 antibody in cancer. *N Engl J Med* 366:2443–2454, 2012.

This article reports on the phase I trial experience with an anti–PD-1 antibody that induced objective responses in 36% of adults with various PD-L1+ malignancies.

162. Brahmer JR, Tykodi SS, Chow LQ, et al: Safety and activity of anti-PD-L1 antibody in patients with advanced cancer. *N Engl J Med* 366:2455–2465, 2012.

Results of a phase I trial utilizing an anti–programmed death–1 (PD-1) ligand antibody to block the PD-1/PD-1L axis that demonstrated durable tumor regressions in 6% to 17% of patients.

168. Weiden PL, Flournoy N, Thomas ED, et al: Antileukemic effect of graft-versus-host disease in human recipients of allogeneic-marrow grafts. *N Engl J Med* 300:1068–1073, 1979.

The first report in support of a graft-versus-leukemia effect in allogeneic hematopoietic stem cell transplantation.

188. Leung W: Use of NK cell activity in cure by transplant. *Br J Haematol* 155:14–29, 2011.

A review of the biology of natural killer cell activity, as well as the conflicting results of clinical studies evaluating the hematopoietic stem cell transplantation outcomes associated with killer cell immunoglobulin-like receptor mismatch, depending on the model used.

197. Ruggeri L, Mancusi A, Capanni M, et al: Donor natural killer cell allorecognition of missing self in haploidentical hematopoietic transplantation for acute myeloid leukemia: challenging its predictive value. *Blood* 110:433–440, 2007.

In an update of the results reported by the same group in 2002, this article includes a total of 112 patients with acute myeloid leukemia who underwent haploidentical hematopoietic stem cell transplantation and shows that in this cohort, donor natural killer cell alloreactivity led to lower relapse rates of patients who underwent transplantation while in complete remission and improved event-free survival in all patients.

203. Venstrom JM, Pittari G, Gooley TA, et al: HLA-C-dependent prevention of leukemia relapse by donor activating KIR2DS1. *N Engl J Med* 367:805–816, 2012.

This article reports that the presence of the activating KIR2DS1 in the donor is associated with a lower relapse risk in adults with acute myeloid leukemia who are undergoing unrelated donor hematopoietic stem cell transplantation.

205. Leung W, Campana D, Yang J, et al: High success rate of hematopoietic cell transplantation regardless of donor source in children with very high-risk leukemia. *Blood* 118:223–230, 2011.

Analysis of single-institution outcomes of pediatric hematopoietic stem cell transplantation in children with very high risk leukemia based on treatment era and donor source. Survival was significantly improved in recent cohorts regardless of donor source, but outcomes for haploidentical stem cell transplantation in recent cohorts were particularly encouraging.

245. Louis CU, Savoldo B, Dotti G, et al: Antitumor activity and long-term fate of chimeric antigen receptor-positive T cells in patients with neuroblastoma. *Blood* 118:6050–6056, 2011.

This article reports on long-term results with an anti-GD2-CAR expressed in Epstein-Barr virus–specific cytotoxic T lymphocytes versus activated polyclonal T cells. Select patients with active neuroblastoma had encouraging results with this approach.

246. Porter DL, Levine BL, Kalos M, et al: Chimeric antigen receptor-modified T cells in chronic lymphoid leukemia. *N Engl J Med* 365:725–733, 2011.

Report of clinical results in three adults with chronic lymphoid leukemia who received CD19 chimeric antigen receptor T-cell

(CART) cells. Apart from promising clinical results, this group demonstrated significant CART expansion and persistence.

250. Brentjens RJ, Davila ML, Riviere I, et al: CD19-targeted T cells rapidly induce molecular remissions in adults with chemotherapy-refractory acute lymphoblastic leukemia. *Sci Transl Med* 5:177ra38, 2013.

 In this study, the authors successfully used CD19 chimeric antigen receptor T-cell therapy to induce molecular remissions in adults with minimal residual disease–positive acute lymphoblastic leukemia.

251. Grupp SA, Kalos M, Barrett D, et al: Chimeric antigen receptor-modified T cells for acute lymphoid leukemia. *N Engl J Med* 368:1509–1518, 2013.

 The first published experience with CD19 chimeric antigen receptor T-cell therapy in two pediatric patients with relapsed, refractory acute lymphoid leukemia. Both patients experienced complete remissions, including one durable complete remission.

273. Leen AM, Bollard CM, Mendizabal AM, et al: Multicenter study of banked third party virus-specific T-cells to treat severe viral infections after hematopoietic stem cell transplantation. *Blood* 121:5113–5123, 2013.

 A report on adoptive therapy with banked third-party virus-specific T cells to treat severe viral infections after hematopoietic stem cell transplantation, which shows a low rate of graft-versus-host disease and striking decreases in viral DNA and resolution of clinical symptoms.

279. Le Blanc K, Frassoni F, Ball L, et al: Mesenchymal stem cells for treatment of steroid-resistant, severe, acute graft-versus-host disease: a phase II study. *Lancet* 371:1579–1586, 2008.

 This study demonstrated efficacy of mesenchymal stem cells in the treatment of steroid-resistant acute graft-versus-host disease, with 30 of 55 patients achievving complete responses and 9 showing improvement.

CONCLUSION

PRINCIPLES OF RADIATION ONCOLOGY

Radiation oncology is an effective and often critical component of multidisciplinary cancer care for many childhood malignancies. The delivery of radiation for the pediatric population is highly complex because of the diversity of patients, tumor location, and biology. Additional concerns regarding the use of radiation for this patient population include a high likelihood of cure, coupled with the well-known and often lifelong complications from oncologic treatment. As survival from childhood cancer has improved, there is better recognition of the impact that long-term toxicities can have on the quality of life for patients. Practitioners have also learned a great deal over the past few decades regarding the required dose of radiation to provide cure, as well as the dose that specific healthy organs can tolerate. For each radiation plan it is now easier to deliver the desired target dose while minimizing the dose to healthy organs, allowing for disease control with decreased morbidity. Still, radiation is not without side effects and for each patient the risks and benefits must be considered to determine an acceptable treatment plan. Multimodality treatment is required for nearly all pediatric cancer patients, and physicians from different subspecialties must work closely together to determine the best management for these children. The desires of children and their parents must be taken into consideration to determine what life-long side effects are considered acceptable in order to achieve the best outcome.

THE PHYSICAL BASIS OF RADIOTHERAPY

Radiation is by no means a novel phenomenon; background radiation is ever-present. The understanding and use of radiation, however, is a relatively recent development in human history. The discoveries of x-rays in 1895 by the German physicist Wilhelm Konrad Röntgen and radioactivity in 1898 by Henri Becquerel led to the recognition of biologic effects of radiation.[1] By the early part of the twentieth century, ionizing radiation had rapidly come into use to treat malignant and benign conditions. At the 1922 International Congress of Oncology in Paris, Coutard presented the first evidence of the use of fractionated radiotherapy to cure advanced laryngeal cancer without disastrous sequelae.[2] This event marked the beginning of the field of radiation oncology.

Ionizing radiation, which includes both particulate radiation and electromagnetic waves, produces ionizations and excitations during the absorption of energy in

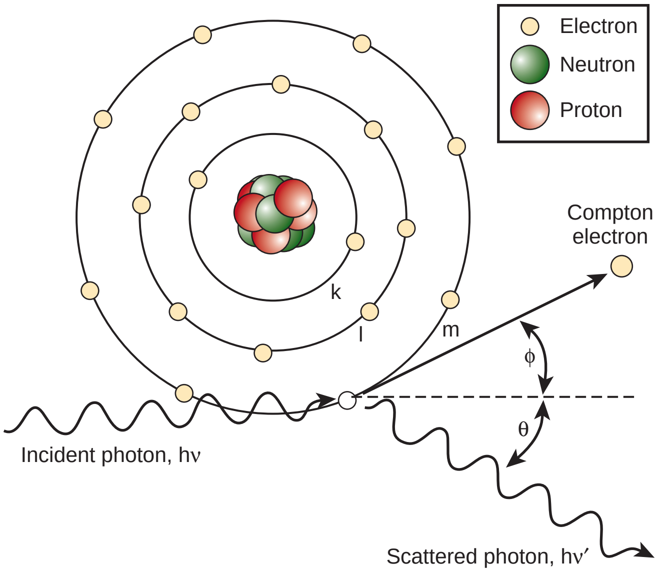

Figure 48-1 The Compton effect.

exposed tissue. Electromagnetic waves are part of a broad spectrum that includes radio waves, microwaves, visible light, x-rays, and gamma rays. In therapeutic radiation oncology, x-rays, gamma rays, and particulate radiation are used. Gamma rays and x-rays share similar general properties, differing in the source and energies. X-rays are produced when charged particles, generally electrons, are accelerated and bombard a high-density target. The target, most commonly tungsten, emits photons of varying energies up to the peak energy of the accelerated electrons. The energy (E) of the photons is determined using the relationship $E = h\nu$, where h is the constant of proportionality known as the *Planck constant*, and ν is the frequency of the wave. Substituting for the frequency, the equation becomes $E = hc/\lambda$, where c is the speed of light and λ is the wavelength. In contrast, gamma rays are emitted by a source; the most commonly used source for gamma rays used in therapeutic radiation is cobalt.

Radiation may be directly ionizing or indirectly ionizing. Direct ionization results in a direct disruption of the atomic or molecular structure of tissue through which the beam of radiation passes. This disruption causes biochemical and molecular damage. Particle beams are directly ionizing. Electromagnetic waves and neutrons are indirectly ionizing; when absorbed in tissue they give up their energy by producing fast-moving charged particles. These charged particles directly damage tissue. Photons in tissue interact in several different ways, including producing the Compton effect or the photoelectric effect, coherent scattering, pair production, and photodisintegration. The dominant reaction, the Compton effect, is governed by the energy of the photons. This process, shown in Figure 48-1, involves the interaction of the photon with a loosely bound orbital electron. Part of the energy of the incident photon is transferred to the electron as kinetic energy; this Compton electron may then interact with electrons in the surrounding tissue. The remaining energy is carried away by another photon that is less energetic than the original photon. The probability of Compton interactions is independent of the atomic number of the target tissue.

Whereas photons interact mainly with orbital electrons, protons, neutrons, and other heavy particles interact with the nuclei of atoms. Heavy particles also cause showers of lower energy and densely ionizing protons, neutrons, and other particles, depositing large amounts of energy over a very short distance. This is referred to as *linear energy transfer (LET)* and depends on the type of radiation used. Photons and electrons both have low rates of energy transfer. Heavy particles tend to deposit their energy in a track over a relatively short distance, and these particles are considered high-LET radiation.

External-beam radiation treatment systems produce ionizing radiation by radioactive decay of a nuclide, most commonly cobalt-60, or electronically through the acceleration of electrons or other charged particles such as protons. In a linear accelerator, electrons are accelerated down a waveguide by the use of alternating microwave fields. In a cobalt-60 unit the source is always on, because radioactive decay occurs continuously. The source is moved to an unshielded position to initiate a treatment. In a linear accelerator, no source is present until the unit is energized; there is an *on* switch and an *off* switch. The energy spectra are different for the two types of treatment units. Cobalt-60 units emit two monoenergetic gamma rays with each decay, producing a discrete spectrum with peaks at 1.17 and 1.33 MeV. A linear accelerator produces a continuous x-ray spectrum with a maximum energy of E_{max} (the accelerating potential) and all other photon energies down to zero. An average x-ray produces the energy of approximately one-third E_{max}. A linear accelerator can produce a treatment beam of electrons as well as photons. The accelerated electron beam exits the treatment unit under controlled conditions of scatter.

The basic components of the treatment machine include a radiation source, a collimating system to form and direct the beam, inherent shielding for protection, a light field to delineate visibly the area being treated, a control system to turn the beam on and off, a system to rotate the beam, and a support apparatus for the patient. Most treatment machines are assembled with isocentric geometry. The isocenter is a point in space at which all of the treatment machine's rotational axes intersect. Any mechanical rotation occurs around an axis that passes through the isocenter.

The linear accelerator has many degrees of geometric movement and can produce a treatment field in almost any orientation relative to the patient. Figure 48-2 shows a photon linear accelerator. The beam source is mounted on a gantry that rotates fully about the patient. The patient is on a treatment couch that can pivot with respect to the plane of gantry rotation. This degree of movement allows multiple fields to approach the target volume. In addition, the collimation assembly mounted on the gantry allows the radiation treatment field to be geometrically conformed to the target volume intersection. The delivery of proton therapy has evolved to utilize a gantry system adapted from linear accelerators and cobalt delivery systems.

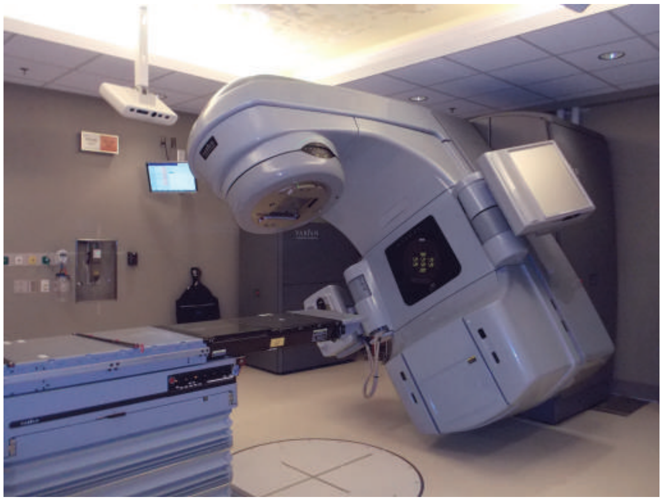

Figure 48-2 Photon linear accelerator. The patient is positioned on a couch *(black table)* that can pivot for patient positioning. The gantry can rotate fully around the patient. The radiation beam can be delivered at almost any orientation desired for treatment.

The amount of energy deposited per unit mass represents the absorbed dose of radiation. The official unit of dose is now the gray, in honor of L.H. Gray, the noted British radiobiologist who discovered the oxygen effect; it replaces the older unit, *rad*. One joule per kilogram is called a *gray (Gy)* and 1 gray equals 100 cGy. Clinical radiotherapy uses external radiation beam delivery, most often x-rays (photons) or electrons. Linear accelerators accelerate electrons to a given energy, generally 4 to 25 MeV; the electrons bombard a target, usually tungsten, resulting in the formation of an x-ray beam. The x-ray beams contain photons of varying energies up to the peak of the accelerated electrons.

In addition to external-beam radiotherapy, other radiotherapy delivery modalities are used in specific circumstances. Implanting radioactive sources directly into a tumor is known as *brachytherapy,* from the Greek *brachys*, meaning *short*. Brachytherapy can involve the placement of encapsulated sources into a body cavity (intracavitary), directly into the tumor or adjacent tissue (interstitial implants), or on the surface adjacent to the tumor (plaque therapy). Permanent implants in the form of radioactive seeds are placed under the guidance of ultrasound, computed tomography (CT), or magnetic resonance imaging (MRI). Temporary implants are performed by using hollow catheters or loading devices inserted at the time of surgery and then subsequently loaded with radioactive sources. The chief advantage of this technique is to deliver a high dose to the target tissue while sparing the nearby normal tissue. Iridium-192 and iodine-125 are the most commonly used radionuclides. Radionuclides are embedded in seeds and sealed in thin plastic strands that can be inserted into afterloading catheters. Iodine-125, with a relatively short half-life of 57 days, is often used in permanent implants. The other feature of iodine-125 that makes it appealing for use in pediatrics is the lower energy of the photons emitted, which simplify the radiation safety concerns compared with iridium-192. There are radiobiological differences between brachytherapy and external-beam radiotherapy. Implants deliver continuous doses of 30 to 100 cGy per hour to the target tissue over the duration of the implant. This is in contrast to external-beam treatment in which the target tissue receives a short pulse of approximately 200 cGy daily, at a dose rate of 100 cGy per minute, over many weeks. Decreasing the dose rate may reduce the cell kill rate of a given dose, because repair of sublethal damage continues throughout the protracted exposure. High-dose-rate brachytherapy techniques are becoming more widely used, although late complications increase with higher dose rates.[3] For dose rates exceeding 1 Gy per hour, a reduction in the total dose is considered. In addition, fractionation of high dose rates can help to diminish the late complications of high-dose-rate delivery.

RADIOBIOLOGY

Mechanisms of Radiation Damage

The biologic effects of ionizing radiation result primarily from the formation of double-strand breaks in cellular deoxyribonucleic acid (DNA). Although most single-strand breaks in DNA caused by radiation are repaired, double-strand breaks can result in irreparable damage that leads to mitotic cell death. Photon radiation (x-rays or gamma rays) can cause damage via direct interaction with the DNA molecule or via the formation of free radicals that subsequently damage the DNA (indirect damage). Charged particles such as helium, carbon, and neon cause damage predominantly through direct interactions. High-energy neutrons interact with the nucleus of an atom, resulting in the creation of densely ionizing recoil protons, alpha particles, and nuclear fragments. LET measures the average energy deposited in tissue per unit distance traveled by a particle or photon. Conventional radiation is sparsely ionizing (low LET), whereas fast neutrons and heavy particles are more densely ionizing (high LET).[4]

Radiation causes complex cascades of molecular events that affect cell cycle checkpoints, apoptosis, DNA damage response, and DNA repair. These effects offer many potential approaches to enhancing radiation damage of tumor cells and to protecting normal tissues. These techniques are discussed in this chapter.

Clonogenic Survival Curves

A typical clonogenic survival curve is shown in Figure 48-3. The surviving fraction is plotted on a logarithmic scale, and the dose of radiation is drawn on a linear scale. The resulting cell survival curve has two distinct regions. In the initial “shoulder” portion of the curve, the fraction of cells killed increases slightly with increasing radiation doses. In the latter part of the curve, killing becomes exponential, which means that a given dose increment kills a constant fraction of cells. The slope of the exponential portion of the survival curve is called the D_0. This term is related to the inherent radiosensitivity of the cell. The smaller the D_0, the more sensitive the cells are to radiation. This is in contrast to radio responsiveness, which refers only to the rate of

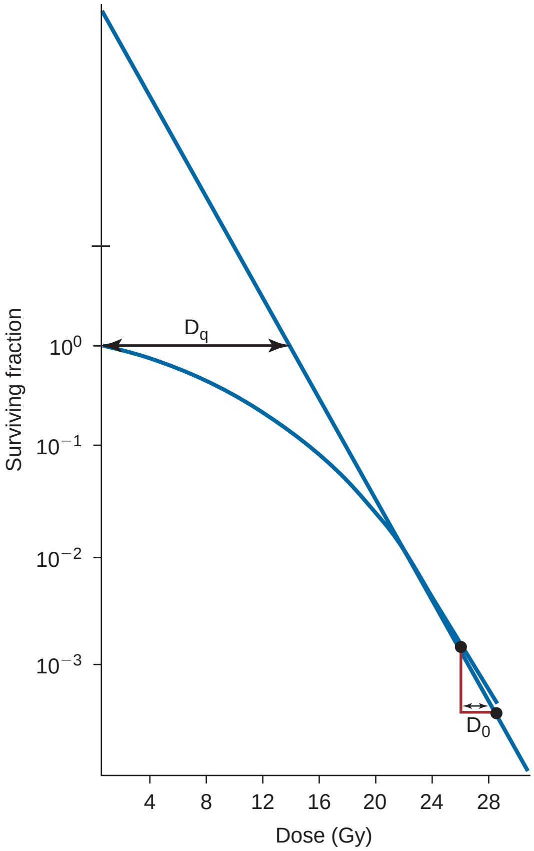

Figure 48-3 Idealized radiation cell survival curve. The fraction of surviving cells is plotted on a logarithmic scale against dose on a linear scale. The D_0 is the dose necessary to reduce the surviving fraction to 0.38 of e^{-1}. The smaller the D_0, the more sensitive the cells are to radiation. The D_q is the quasi-threshold dose and is a quantitative measure of the sublethal repair capability. *(Modified from Hall EJ:* Radiobiology for the radiologist*, ed 2, Hagerstown, Md., 1978, Harper Row.)*

disappearance of a tumor after irradiation and has no correlation with the innate sensitivity of the cells. The D_0 for mammalian cells in vitro generally falls between 1 and 2 Gy. The relatively narrow range of values for widely varying types of cells is striking. The initial nonexponential portion of the curve is believed to result from the capacity of most mammalian cells to repair nonlethal radiation injury. Saturation of the repair capability is thought to occur at the point where killing cells becomes exponential.[4]

Additional mathematical models have been used to characterize the cellular response to ionizing radiation. One of the most commonly used models, the linear-quadratic survival model, is routinely used to investigate how different tumor repopulation kinetics between radiation treatments influence the scheduling of radiation treatment. As various fractionation schemes have been examined clinically, including hyperfractionation, accelerated fractionation, and combined modality therapy (chemoradiation), the linear-quadratic model has been used to calculate the tolerability of specific tissues to various radiation schedules.[5] The concept of the biologically effective dose, a tool offered by the linear-quadratic model, allows quantification of the effects of radiation schedules on tumors and on normal structures.[6] Although this model has been helpful when applying alternative fractionation schemes to patient treatment, caution must be exercised in its application, because features such as faster tumor growth rate and higher repair capacity result in greater variations in the outcome of the survival fraction. Gaps in treatment, planned or unplanned, also accentuate the differences in the survival fraction under varying growth dynamics.[7] These limitations notwithstanding, mathematical modeling of the cellular response to radiation has contributed greatly to the clinical application of radiation to combating malignancies.

The Oxygen Effect

Tissue oxygenation influences the response of tumors and normal tissues to ionizing radiation. Poorly oxygenated tissues are two to three times more resistant to radiation than are normally oxygenated tissues. Oxygen is thought to mediate indirect damage, combining with free radicals to make DNA damage irreversible. The effect of oxygenation is measured by the oxygen-enhancement ratio. This is the ratio of doses under hypoxic versus aerated conditions required to produce a given level of cell kill. As LET increases, the effect of oxygen enhancement decreases.[4]

Radiation Interactions with Chemotherapeutic Agents

A number of chemical substances may alter the radiation response of a cell.[8] The effects may be additive, such as those of most alkylating agents and antimetabolites, or they may be synergistic, such as those of the antibiotic dactinomycin.[9] Doxorubicin and dactinomycin markedly reduce the shoulder region of the radiation cell–survival curve.[9] Dactinomycin also steepens the slope of the exponential portion of the cell-survival curve and potentiates the radiation effect; thus it is thought to be a true radiation sensitizer.

Combining radiation and chemotherapy can achieve better clinical outcomes than either modality alone but can also potentiate toxicities to normal tissues. Interactions between chemotherapy and radiation can increase the risk for toxicity in normal tissues, even when the two modalities are temporally spaced. In 1959 Dr. G.J. D'Angio described an interesting yet enigmatic phenomenon termed *radiation recall*. Radiation recall describes the remembering, or reemergence, of an inflammatory reaction that occurs within the radiation field and is prompted by the administration of particular agents days to years after initial radiation exposure. In the original case described by D'Angio, dermatitis emerged within the radiation field after application of actinomycin D to the skin.[9] Although radiation recall is most commonly documented as skin reactions, other tissues and organs are also susceptible to this phenomenon, including oral and intestinal mucosa, larynx, lungs, muscles, and the central nervous system (CNS).[10] The cause of radiation recall remains poorly understood. Although timing and dosing factors clearly impact the risk and severity of the recall reaction, there is no clear radiation dose threshold.

TECHNOLOGICAL ADVANCES IN RADIATION ONCOLOGY

All technological advances in radiation oncology allow for improved dose delivery to the target or tumor and/or better avoidance of healthy tissues outside of the area at risk of disease recurrence. The field of radiation has benefited from many major developments over the past several decades in the fields of diagnostic radiation and physics, allowing for markedly improved radiation delivery to pediatric cancer patients.

The advent of three-dimensional (3D) imaging with the invention of the CT scanner in 1971 opened a new world for not only diagnostic imaging but also for radiation treatment planning.[11] The ability to define structures and tumors in 3D and to place radiation fields and beam angles with this enhanced information marked a major advancement for the field. Additional imaging developments including MRI and positron emission tomography (PET) further enhanced capabilities to define the area at risk for tumor recurrence. Most radiation centers obtain CT scans in the radiation oncology department in the desired treatment position and employ fusion software to fuse MRI and PET scans to assist in target delineation. Figures 48-4 and 48-5 show fusions used for radiation planning. By defining this region more accurately, practitioners not only improve disease control but can also decrease the volume of healthy tissue receiving unnecessary radiation. Before the use of CT, radiation oncologists used x-rays to plan fields, and beam arrangements were less well guided by anatomic detail. Because of the inability to define tumors as precisely, fields of radiation were large for fear of local recurrence. In addition, the inability to evaluate radiation plans in 3D made the details of dose deposition less clear. Without 3D imaging radiation oncologists would not have been capable of developing the many advanced treatment delivery techniques such as intensity modulated radiotherapy (IMRT) and stereotactic radiotherapy (SRT) that are widely available today.

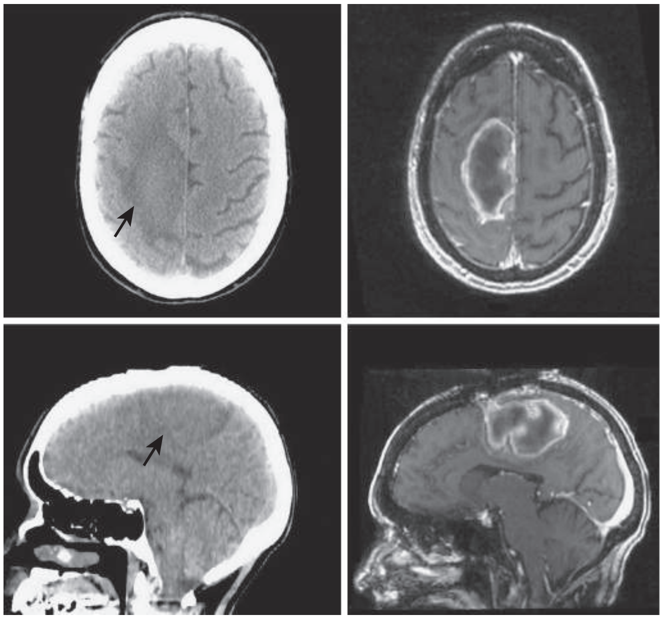

Figure 48-4 CT axial and sagittal images (*left upper* and *lower panels*) and MRI T1 post-gadolinium axial and sagittal images *(right)* showing brain tumor *(arrows)* that is much more easily visualized on MRI sequences. Fusion software enables more accurate delineation of tumor volumes by registering images together.

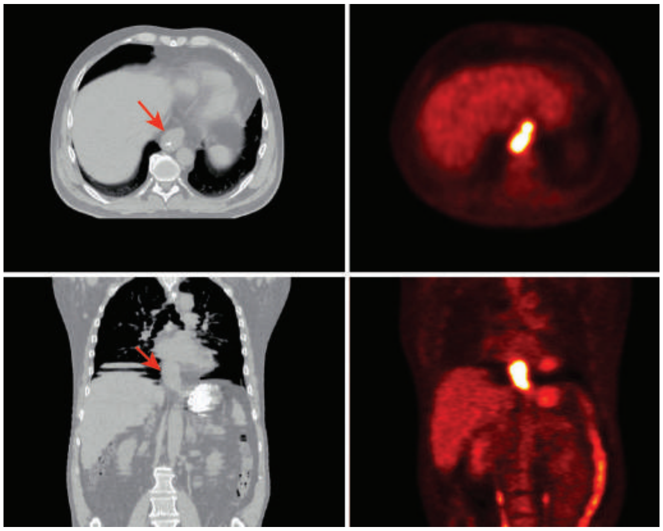

Figure 48-5 CT axial *(upper)* and coronal *(lower)* images *(left)* and PET images *(right)*. Fusion software allows for registration of PET images to planning CT so that PET avid disease *(arrow)* can be easily defined on planning CT images. Due to respiratory motion, accurate fusion can be more challenging in the chest and abdominal region.

Conformal radiotherapy describes treatment that delivers a high-dose volume that is shaped to conform to the target volume while minimizing the dose to critical normal tissues in the adjacent area. Because conformal radiotherapy attempts to conform the dose to the target, careful and accurate delineation of the target is critical. Patient immobilization for setup accuracy and to limit patient motion is imperative. The International Commission on Radiological Units and Measurements-50 defined target volumes that are used in treatment planning.[12] The gross tumor volume (GTV) is the volume of macroscopic tumor that is visualized on imaging studies. The clinical target volume (CTV) is the volume that should be treated to high dose, typically incorporating both the GTV and the surrounding tissues assumed to be at risk because of microscopic spread of the disease. The planning target volume (PTV) is the volume that should be treated to ensure that the CTV is appropriately covered; this takes into account systematic and random setup errors between treatments and during treatment (Fig. 48-6). The treated volume is the volume of tissue enclosed by a specific isodose line. The treated volume is greater than the PTV.

Intensity-Modulated Radiotherapy

Sophisticated planning techniques have significantly improved the ability to tailor the radiation field to the desired treatment region. IMRT is one such novel technique that allows the radiation oncologist to modulate the intensities of individual beamlets within each beam. IMRT requires highly sophisticated software that allows physicians to indicate the desired doses to tumor volumes and organs. This software then runs multiple iterations

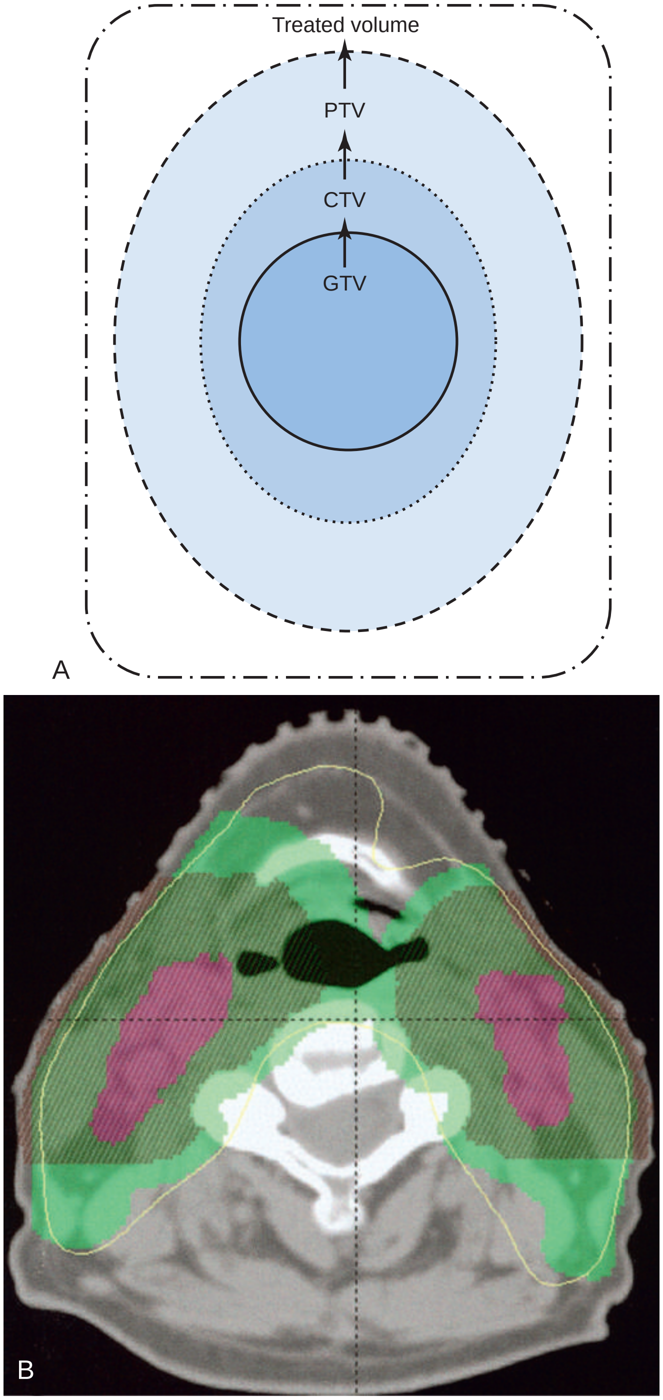

Figure 48-6 **A**, Target volumes for treatment planning. *CTV,* Clinical target volume; *GTV,* gross tumor volume; *PTV,* planning tumor volume. **B**, Axial CT image showing contoured target structures. Gross target volume shown in *pink*; CTV *hatched*; PTV in *green*.

of treatment plans involving numerous small fields and several beam angles. The physician either accepts the optimized plan or provides new parameters until the desired dose distribution has been met. IMRT accomplishes excellent conformity to target volumes while decreasing the high dose to nearby critical structures. Figure 48-7 demonstrates an IMRT field arrangement and plan for a young child with a localized ependymoma.

Stereotactic Radiotherapy

Stereotactic radiosurgery (SRS) is delivery of radiation to a target in a single treatment. This is generally reserved for smaller brain tumors, although stereotactic body radiosurgery has been developed in recent years. SRS is accomplished by delivering multiple small beams of radiation in order to deliver the prescription dose to the target but a much lower dose to the surrounding tissues. Precision is of paramount importance for SRS, and typically rigid frames and fiducial markers are used. Several delivery systems exist for photon-based SRS (e.g., Gamma-Knife, X-knife, Cyber-Knife). Protons can also be used to deliver SRS. Stereotactic treatments may also be delivered over several fractions; this is generally referred to as *SRT* (stereotactic radiation treatment). Figure 48-8 shows an SRS plan.

Proton-Beam Radiation

Proton-beam radiation is a form of particle radiotherapy that allows for deposition of maximum dose at a great range of depths (up to 32 cm) and complete sparing of tissues beyond the area of maximum dose deposition.[13] This is in contrast to photons that are limited in the depth at which they deliver maximum dose (less than 3 cm) and

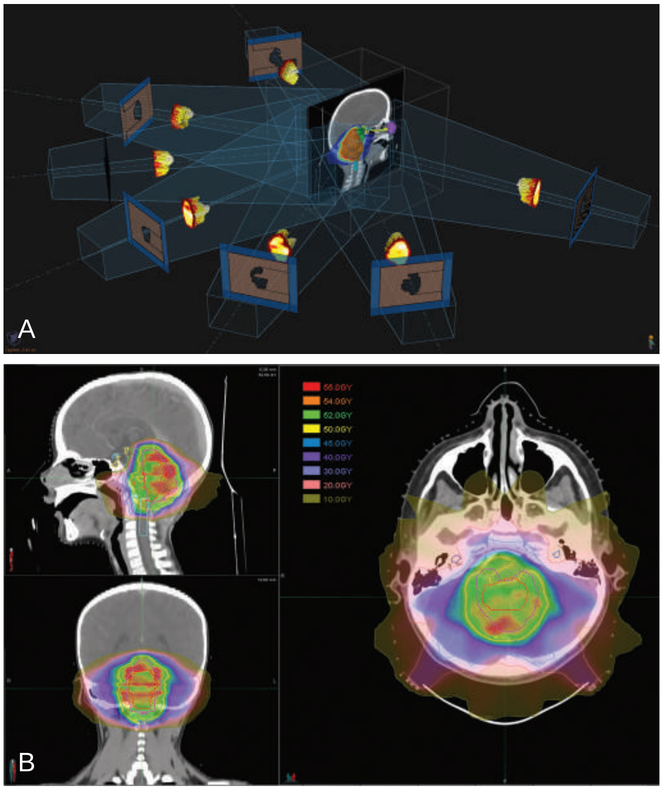

Figure 48-7 **A**, Multiple beam angles each deliver many small rays or beamlets of radiation that are used to conform the high dose to the target volume and minimize the high dose to avoid structures for this IMRT plan for a localized infratentorial ependymoma. **B**, Treatment plan showing dose distribution for the aforementioned beam arrangement demonstrating the high-dose region conforming very tightly to the target volume and reduced dose to critical structures such as the cochlea. This dose distribution would not be achievable with standard photon therapy.

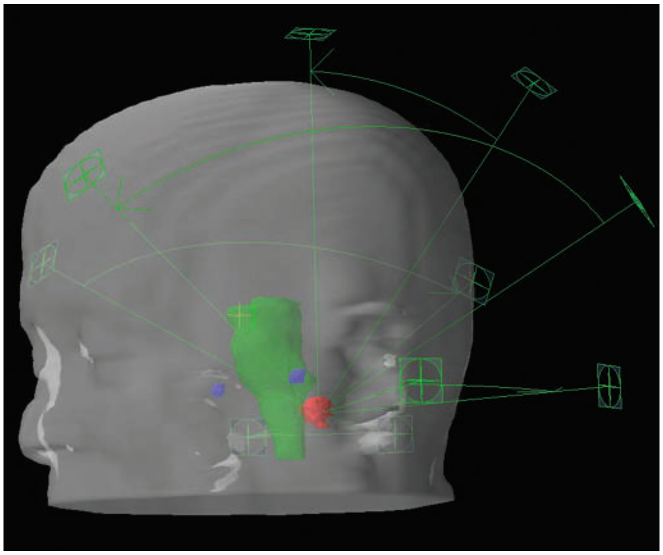

Figure 48-8 Multiple small beams of radiation deliver radiation to a small brain tumor while delivering a low dose to the surrounding healthy brain, often allowing for delivery of radiation in a single fraction.

continue to deposit the dose until passing through and exiting the body. A single proton beam delivers a small and relatively constant dose until near the end of its range, when the majority of the dose is delivered in the Bragg peak. Beyond this point, no dose is delivered.[14] Because a single Bragg peak covers only 0.5 to 1 cm, multiple Bragg peaks are required to treat a tumor.[14] CT planning is required for proton planning, because the impact of tissue inhomogeneity is greater and the density of the tissue must be taken into account by converting Hounsfield units to proton stopping power. For clinical treatment, proton beams are either combined to form a spread out Bragg peak (SOBP; 3D conformal/scattered proton treatments), or multiple proton beams are scanned across the target volume (scanning beam technique). 3D conformal radiotherapy (CRT) with protons requires patient-specific hardware to shape, or conform, the beam to the target. Lucite compensators shape the distal edge of the beam to the target volume and correct for changes in tissue density, and brass apertures or multileaf collimators shape fields to the target volume laterally. Figure 48-9 shows the delivery of 3D CRT proton treatment for a child using brass apertures and Lucite compensators. When multiple inhomogeneous scanning beam fields are used to treat a target volume, the term *intensity-modulated proton therapy (IMPT)* is used. Figure 48-10 demonstrates the use of multiple inhomogeneous beams for an IMPT plan.[15,16] Proton radiation is prescribed in gray radiobiological equivalents (Gy [RBE]) as opposed to Gy, which is used for prescribing photon radiation.[17,18] The Gy (RBE) takes into account a slightly higher average relative biologic effectiveness. Therefore the prescribed dose and biologic effects of protons are predicted to be equivalent to photons. The difference between protons and photons is the physical dose distribution. These physical properties of protons allow for a reduction in both high and low doses of radiation exposure.

In recent years, proton therapy has received much attention as a therapy that has the potential to drastically reduce late morbidity for children. Proton therapy is, however, much more capital-intensive and operationally expensive than traditional photon-based therapy. The high costs of a proton facility can be prohibitive, and for this reason proton centers are available at only a limited number of facilities. Although there has been a recent growth in the use of proton radiation both in the United States and abroad, this form of radiation is still capacity-constrained and physicians must select patients that will benefit most from this form of radiation. Children who are thought to benefit most from the tissue-sparing characteristics of proton therapy include very young children with curable tumors. Locations in the body that may benefit more from this highly conformal modality include the brain and the head and neck region. Additional malignancies and anatomic sites may also receive benefit from this form of radiation.

Image-Guided Radiotherapy

To address patient immobilization and daily positioning, some centers are using image-guided techniques. Image-guided radiotherapy (IGRT) allows the radiation oncologist

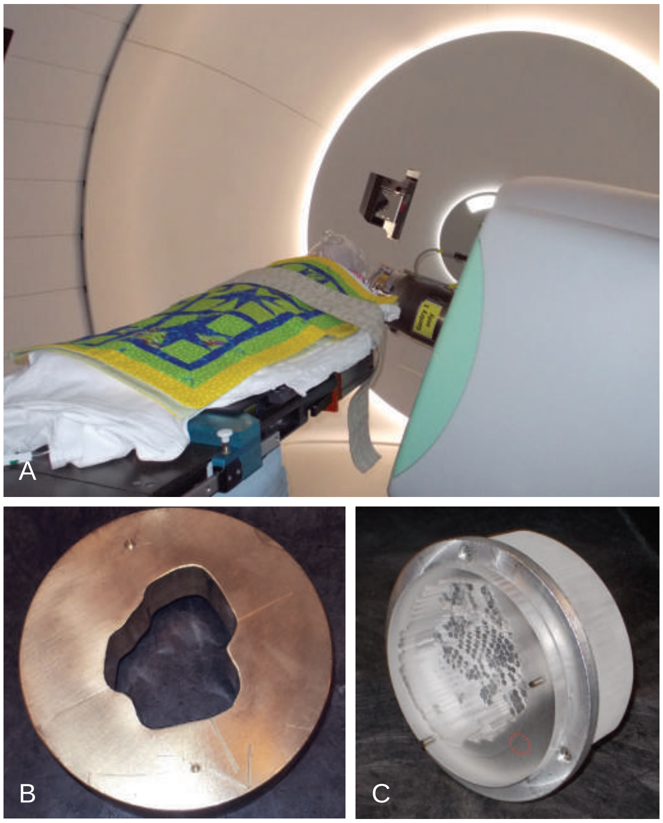

Figure 48-9 **A**, An anesthetized child receiving 3D conformal proton radiation for a brain tumor. For each field a custom brass aperture and Lucite compensator is mounted to the end of the gantry (snout). Anesthesia is required for young children to ensure that there is no movement during treatment. **B**, Brass aperture custom made to shape the field to the tumor and block healthy tissues outside of the tumor. **C**, Lucite compensator custom made to correct for tissue inhomogeneity and to shape the distal edge of the proton SOBP to the tumor.

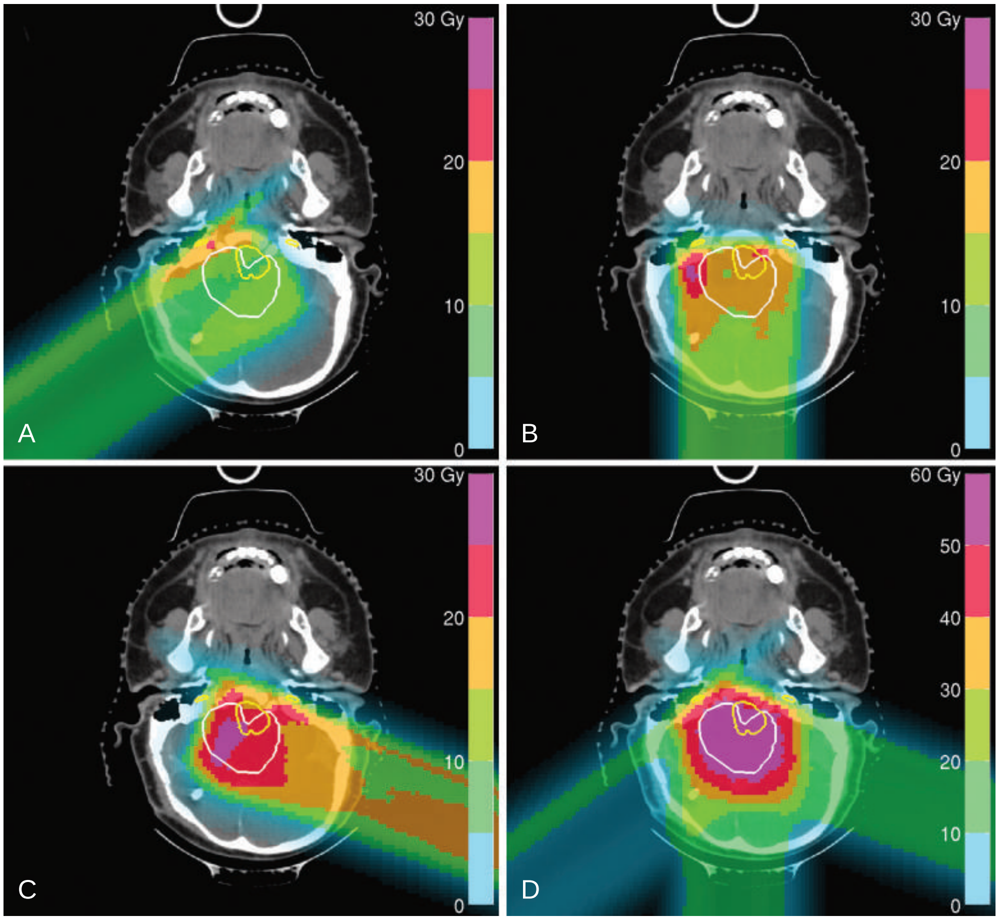

Figure 48-10 Three inhomogeneous fields composed of thousands of individual Bragg peaks are used to create a homogenous dose distribution for the composite IMPT plan. **A**, Right posterior field. **B**, Posteroanterior field. **C**, Left posterior field. **D**, Composite dose distribution of the three fields. The color scales for images **A**, **B**, and **C** are identical.

to confirm the tumor location every day. One technique to minimize tumor and patient movement is the use of a CT image of the patient using the "cone beam" technique that allows the generation of an image of the tumor and all surrounding normal structures using the same linear accelerator with which the patient is being treated. Appropriate adjustments can then be made daily to assure that the tumor is receiving the appropriate dose of radiation and normal tissues are receiving doses within their tolerance range. Gold seeds can be implanted into or near a tumor. The seeds can be tracked during the treatment. The technique of tracking the tumor during respiration and treating it at a particular phase of breathing is called *gated,* or *breath-synchronized radiotherapy* (BSRT) IGRT. This is also known as *four-dimensional (4D) IGRT.* (The fourth dimension is time.)

CLINICAL TREATMENT WITH RADIATION

Radiation is used for a wide variety of indications and disease sites. The decision to include radiotherapy in the management of a particular childhood malignancy, as well as the radiation dose used and volume treated is individualized for each patient and is dependent on many patient-specific and tumor-related characteristics. Primary among these are age, biology, stage of the cancer, and tolerance of surrounding normal tissues. Radiation delivery may also depend on surgical and other adjuvant treatments. The full management of each malignancy is beyond the scope of this chapter and the reader is referred to the chapters dedicated to the specific disease sites for a full description of disease manifestations, work up, staging, and details of therapy other than radiation.

Central Nervous System Malignancies

Tumors of the CNS are the most common pediatric malignancy requiring radiotherapy. The use of radiation dose and volume is highly dependent on pathology, extent of resection, and dissemination of disease. Given the numerous critical structures in close proximity to brain tumors including the developing brain, hypothalamus, pituitary gland, visual, and auditory structures, it is highly preferable to choose a conformal modality for children who have a good prospect of long-term survival. The use of MRI to delineate target areas is crucial for this location. The use of 3D conformal planning has markedly increased capabilities for the treatment of CNS malignancies. Advanced radiation modalities including IMRT, Tomotherapy, SRS/SRT, Gamma-Knife, and proton therapy are often employed for treatment of these malignancies.

Medulloblastoma Supratentorial Primitive Neuroectodermal Tumors

Medulloblastoma, an embryonal tumor located in the cerebellum, is a common pediatric brain tumor for which radiation is an important component of curative treatment.[19] Disease extent is categorized as *standard-risk* or *high-risk,* with standard risk defined as nonmetastatic disease in children over the age of 3 with 1.5 cm^2 or less of residual disease after surgery; all others are considered to have high-risk disease. Although not included in the stratification, anaplastic histology has been shown to carry an inferior prognosis compared with classic medulloblastoma. Molecular subtypes will likely be incorporated into future stratification, which will impact radiation dose as research indicates that prognosis is contingent on molecular characteristics.[20,21] Supratentorial primitive neuroectodermal tumors (SPNETs) are embryonal tumors located in the cerebrum. The treatment for SPNETs is the same or similar to that for high-risk medulloblastoma. Patients with medulloblastoma or SPNET have a high risk of relapse in the cerebrospinal axis even if gross disease is not detected on imaging or in spinal fluid, and patients over the age of 3 years should receive craniospinal irradiation (CSI) as a component of treatment. For patients with standard-risk disease, 23.4 Gy CSI and a boost to the area of primary disease or posterior fossa to a dose of 54 Gy is recommended. Cure rates for these patients exceed 80%.[22] Outcomes are less favorable for patients with high-risk medulloblastoma and SPNET, with cure rates on the order of 60% to 70%. These patients should receive 36 Gy CSI with a boost to the primary tumor bed or posterior fossa to 54 Gy.[23-25] For medulloblastoma, the standard volume to boost is the whole posterior fossa. Although the involved field boost has become customary at some institutions, it is not yet considered to be standard of care at the time of publication, as results from the Children's Oncology Group (COG) study, *ACNS0331,* were not available.[26] This study randomized all children enrolled to whole posterior fossa radiation versus involved field radiation. This protocol also randomized standard-risk patients under the age of 8 to reduced-dose CSI (18 Gy) versus standard dose radiation (23.4 Gy). For children with high-risk medulloblastoma or SPNET, the COG protocol *ACNS0332* is evaluating the addition of daily carboplatin as a radio sensitizer concurrent with radiation and posttreatment isotretinoin.[26] Modern techniques including IMRT, Tomotherapy, and proton radiation can decrease the dose and/or volume of uninvolved tissues receiving radiation. Figure 48-11 demonstrates the ability of protons to eliminate exit dose to organs anterior to the vertebral bodies for children receiving CSI.

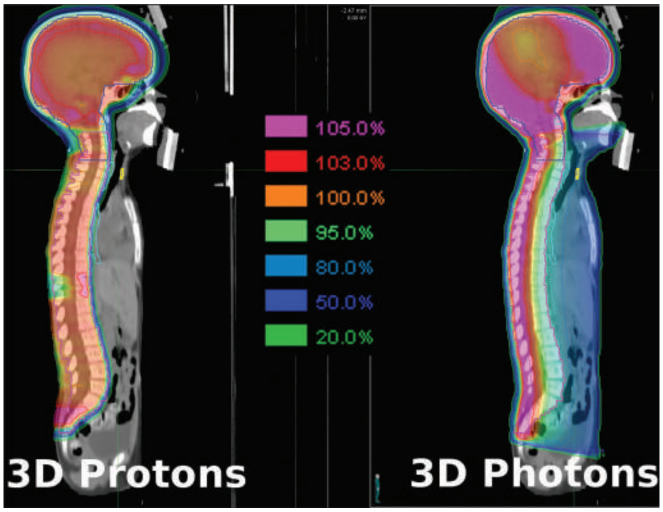

Figure 48-11 CSI delivered with protons versus photons. Protons deliver the dose to a chosen depth with no dose delivered beyond this point. This allows for sparing of all organs anterior to the vertebral bodies. Note that the entire vertebral body is treated to an even dose to prevent asymmetric growth for children who have not yet reached full height. The photon plan delivers unnecessary dose to the thyroid, heart, lung, gastrointestinal tract, and ovaries.

For children under the age of 3 years, CSI is considered to lead to unacceptable neurocognitive outcomes, and for this reason treatment of these children generally consists of chemotherapy first to delay radiotherapy, and the subsequent radiation volume is often limited to the involved field or sometimes even omitted if the child is under age 3 years at the time of radiation and did not have metastatic disease.[27,28] Outcomes are inferior, perhaps to a large extent because of the omission, deferral, or alteration of radiotherapy. The COG study *ACNS0334* delivers intensive chemotherapy, including high dose chemotherapy and stem-cell rescue. Radiation is optional on this trial, and when used it calls for delivery of radiation to the involved field to a dose of 50.4 to 54 Gy. Again, highly conformal techniques are recommended to achieve sparing of CNS structures from unnecessary radiation.

Low-Grade Glioma

Astrocytomas are the most common pediatric CNS tumor. Complete surgical resection can be achieved in many cases. With cure rates exceeding 90% for complete surgical resection, radiation is not required. Low-grade gliomas of the thalamus, hypothalamus, optic chiasm, tectum, or other region that is not amenable to complete resection may require radiation. Although observation may be appropriate if the child is asymptomatic, progression of the tumor will likely occur and treatment will be required at some point. Chemotherapy is also considered, although for the majority of patients this is only a temporizing measure. In general, chemotherapy is used for young patients, whereas radiation is the first choice for older patients, but there is no clear specific age to determine the appropriate treatment modality. Treatment decisions for these patients are best made in a multidisciplinary setting. Chemotherapy may allow for neurocognitive development and delay neuroendocrine or other radiation-related side effects, but there is a high risk of tumor progression that may lead to irreversible loss of function. Radiation, although more definitive, carries neurocognitive, neuroendocrine, and other risks. When radiation is used, a dose of 50.4 to 54 Gy is recommended. The treatment volume includes all gross tumor and the tumor bed as seen on MRI. Because many low-grade gliomas either do not enhance at all or have a nonenhancing component,

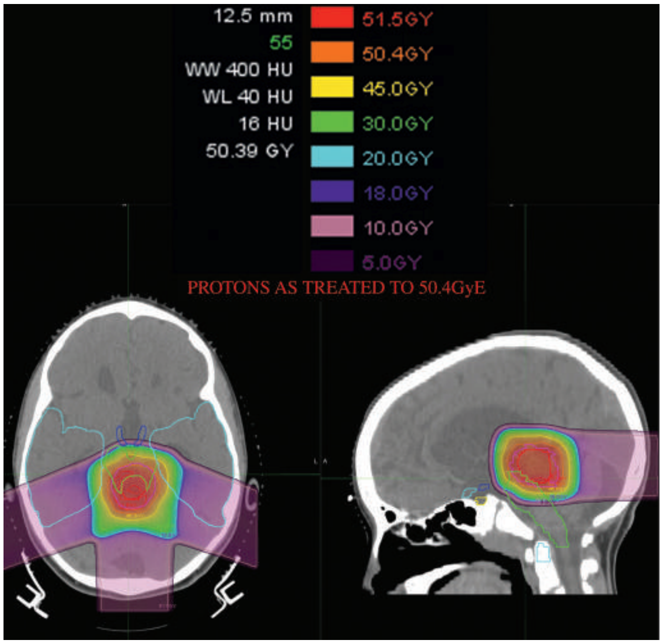

Figure 48-12 3D Conformal proton plan for a tectal glioma showing sparing of the temporal lobes and hypothalamus and pituitary gland. Protons reduce low- and high-dose radiation delivered to healthy structures of the brain.

care should be taken to include all areas of T2 abnormality that are suspicious for tumor. T2 fluid-attenuated inversion recovery (FLAIR) sequences are often useful. A margin of 5 mm to account for areas of potential microscopic disease is recommended for well-demarcated tumors. Excellent long-term outcomes have been documented after CRT.[29] Figure 48-12 shows a proton plan for a tectal glioma.

Anaplastic Astrocytoma/Glioblastoma Multiforme/Diffusely Infiltrating Pontine Glioma

Anaplastic astrocytoma and glioblastoma multiforme (GBM) carry a poor prognosis compared with other pediatric brain tumors, although long-term survival may be achieved for some patients.[30] Surgery followed by radiation with or without chemotherapy is standard. Initial treatment volumes typically include T2 FLAIR changes and enhancing tumor plus a margin for radiographically occult tumor. This volume is treated to a dose of 45 Gy. The tumor volume is then reduced to the gross tumor with a margin to deliver a total dose of 54 Gy to 59.4 Gy to this region, depending on age and adjacent critical structures.

Another highly malignant tumor is a diffusely infiltrating pontine glioma (DIPG). These tumors arise in the pons and have a classic appearance on MRI of a nonenhancing T2 bright lesion that expands the pons. Radiation is indicated for treatment of this disease, and response is typically prompt. Many patients experience a reversal of observed neurological symptoms when treated to a dose of 54 Gy. Unfortunately, response is not durable and symptoms typically recur several months after radiation. The median survival for these children is 1 year, and cure is not achievable with current available treatment.

Craniopharyngioma

Craniopharyngiomas are histologically benign tumors that can be locally destructive, causing neuroendocrine and visual disturbances. When resection is incomplete, most of these tumors recur, so radiotherapy is generally recommended. Limited surgery and radiation leads to excellent rates of control in excess of 90%. Target volume includes residual solid and cystic components and the postoperative bed with a margin of approximately 5 mm for microscopic disease. A dose of 50.4 to 54 Gy is recommended. These tumors typically have a cystic component that may change in volume during radiation, and a quick T2 MRI (Half-Fourier Acquisition Single-Shot Turbo Spin-Echo [HASTE] sequence) or CT during radiation treatment is advised so that the radiation plan can be adjusted to ensure that the cystic component remains in the treatment field with maximal sparing of uninvolved tissue. Highly conformal techniques are recommended to provide better sparing of the surrounding brain. Given neuroendocrine structures are involved by tumor, it is rarely possible to provide sparing of these structures even with the most conformal of modalities.

Ependymoma

Intracranial ependymoma represents 5% to 8% of pediatric brain tumors. The majority of these tumors arise in the fourth ventricle with fewer occurring in the supratentorial brain. Standard treatment for nondisseminated disease consists of maximal surgical resection followed by involved field radiotherapy even for children under the age of 3 years. With surgery and CRT, long-term local control rates of approximately 80% have been achieved.[31,32] Trials attempting to use chemotherapy and omit radiation have led to inferior outcomes, although chemotherapy may be recommended after a subtotal resection in attempt to allow for a second surgery and complete resection. Radiotherapy is prescribed to the tumor bed plus a margin of approximately 5 to 10 mm. Care must be taken to carefully delineate the tumor bed and areas that the tumor was in contact with before surgery as well as any areas of residual gross disease. The prescribed dose is 54 Gy to 59.4 Gy in 30 to 33 fractions to this volume. The COG protocols (*ACN0121* and *ACNS0831,* respectively) prescribe a total dose to 59.4 Gy, but *ACNS0831* requires that critical structures outside of the area of highest risk be blocked after 54 Gy.[26] Given the young age of these patients, it is important to use a very conformal technique to avoid the normal developing brain, cochlea, and neuroendocrine structures. The use of 3D CRT, IMRT, and protons has been shown to provide superior sparing of nearby critical structures while maintaining excellent outcomes.[31,32] Whereas local recurrence accounted for the majority of recurrences in historical series, recent patterns of relapse show a trend towards a more even ratio of distal and local recurrences but no absolute increase in distal recurrences; this is a reflection of the improved local control achieved as a result of advances in surgery and radiation.[31,32a]

Germ Cell Tumors

CNS germ cell tumors (GCTs) are midline CNS tumors that typically arise within the infundibulum or pineal gland but can occur elsewhere in the brain.[33] GCTs are divided into two main histologic subgroups that are highly prognostic; pure germinomas and GCTs with nongerminomatous components (NGGCTs). Pure germinoma is the most common type of GCT and typically holds the most favorable prognosis. Excellent outcomes can be achieved with radiation alone or a combination of radiation and chemotherapy. Whole-ventricle radiotherapy to a dose of 24 Gy followed by a boost to the tumor bed to total 45 Gy to 50 Gy is considered a standard treatment for pure germinoma. With the use of chemotherapy before radiotherapy, the radiation dose may be reduced, but attempts to reduce volumes to the primary tumor bed have led to an increased rate of in the ventricles. After a complete to near-complete response to chemotherapy, whole-ventricle radiation to a dose of 21 Gy followed by a dose to the tumor bed to 30 to 36 Gy is most standard. The COG protocol *ACNS1123* is investigating the use of chemotherapy followed by radiotherapy to a dose of 18 Gy to the whole ventricles, which is then followed by a boost to a total of 30 Gy for localized pure germinomas showing a good response to chemotherapy. For patients with disseminated pure germinoma, the prognosis is still excellent with radiation alone or chemotherapy followed by radiation. Doses are generally the same as stated above; however, the volume at risk for microscopic disease is the entire craniospinal axis rather than the whole ventricle. NGGCT carries a less favorable prognosis, and combined modality treatment is standard. The COG study *ACNS0122* delivered 6 cycles of induction chemotherapy (carboplatin, ifosfamide, and etoposide) followed by CSI to 36 Gy and an involved field boost to 54 Gy. Early reports suggest excellent outcomes. Reducing the volume and dose of radiation for patients who have NGGCT with localized disease and an excellent response to chemotherapy in attempt to decrease toxicity is the goal of the COG trial *ACNS1123,* which delivers the same chemotherapy as *ACNS0122* followed 30.6 Gy to the whole ventricles and 54 Gy to the tumor bed. Patients with disseminated disease still receive CSI and are not eligible for this study. A whole ventricular atlas is available on the Quality Assurance Review Center (QARC) website to help delineate this structure consistently for *ACNS1123.* Figure 48-13 shows images from this atlas.

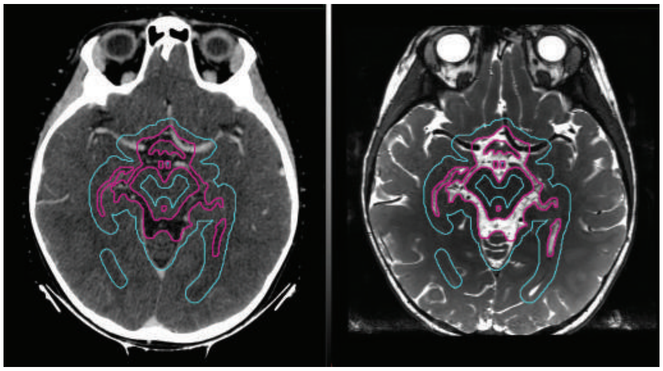

Figure 48-13 CT image *(left)* and fused T2 MRI image *(right)* showing contours for the ventricle volume. Ventricle volume is in *magenta* and PTV is in *cyan.*

Atypical Teratoid/Rhabdoid Tumors

Atypical teratoid/rhabdoid tumor (AT/RT) is a highly malignant, small, round, blue cell tumor that has only recently been recognized as a distinct entity since discovery of the tumor suppressor gene, *INI1.* Initial reports suggested a dismal prognosis for children with AT/RT, but studies incorporating high-dose chemotherapy have shown markedly improved outcomes compared with historical series.[34,35] Maximum surgical resection, high-dose chemotherapy with stem-cell rescue, and early radiation provide the best chance of cure.[35] Children diagnosed with AT/RT are generally very young, and children under the age of 3 years should receive involved field radiation to a dose of 50.4 to 54 Gy with highly conformal techniques.[36] Early radiation and CSI for children older than age 3 years seem to lead to improved outcomes and are generally recommended.[37]

Spinal Tumors

Primary spinal cord neoplasms are rare in children, accounting for approximately 5% of CNS malignancies. Most tumors are either low-grade astrocytomas or myxopapillary ependymomas. Surgical resection is the primary treatment, and radiation is reserved for situations when either complete resection is not possible or in the setting of tumor recurrence. The prescribed dose is typically 45 to 54 Gy based primarily on spinal cord tolerance, risk of relapse, and patient age.

Hematologic Malignancies

Advancements in cancer therapy have led to extraordinary improvements in outcomes for children with hematologic malignancies. Management has also greatly changed over the past few decades. Survival is excellent for children with Hodgkin disease (HD), non-Hodgkin lymphoma (NHL), and acute lymphoblastic leukemia (ALL).[38] Contemporary therapy places an emphasis on risk adaptation and avoidance of treatment-related complications while maintaining high rates of cure.[38,39] Children with hematologic malignancies are currently treated with combinations of cytotoxic chemotherapy and sometimes radiation. Advances in chemotherapy over the past several decades has allowed for a reduction in radiation dose and volume for those patients requiring it.

Hodgkin Disease

HD is a highly curable tumor with radiation alone or combined modality therapy. Contemporary treatment utilizes risk-adapted treatment with chemotherapy followed by response-based volume and dose-reduced radiotherapy. Radiotherapy alone was the first curative therapy established for HD, but the high doses used and large volumes treated with radiation led to substantial late morbidity including musculoskeletal developmental abnormalities, cardiac morbidity, and second malignancies. Many pediatric trials related to HD focus on tailoring chemotherapy and radiation to provide adequate disease control while minimizing late effects of treatment.[38,40,41] Most patients are treated with multiagent chemotherapy followed by involved field radiation to 15 to 25.5 Gy. Many studies are investigating response-adapted radiation or the omission of radiation for patients with disease showing an early favorable response to chemotherapy. Radiation volumes have been successfully reduced to the involved field, defined as a region of lymph nodes including and in close proximity to the disease as defined by diagnostic imaging. Standard involved field guidelines defining radiation field borders by anatomic landmarks are available.[42] Involved nodal radiation is being used on several trials.[43] This treatment involved contouring the areas that contained abnormal or PET-positive lymph nodes and adding a margin to these nodes to define the target for treatment. The EORTC-GELA group has established guidelines for this treatment.[43]

Leukemia

Leukemia, most often ALL, is the most common pediatric malignancy. Despite the commonality of this disease, radiation oncologists, because the development of more effective chemotherapeutic regimens, see children with leukemia less often. At present, radiation is used only in the setting of high-risk disease, refractory disease, or relapse. For patients with B-cell ALL, current guidelines indicate radiation for patients with the following high-risk features; WBC > 100,00, CNS3 disease (>5 WBC/micro-liter or blasts in the cerebrospinal fluid [CSF]), Philadelphia translocation t(9;22) ALL, T-cell phenotype, or other high-risk disease with poor response to induction chemotherapy.[44] Cranial radiation to a dose of 12 to 18 Gy is recommended. The other site for which radiation may be necessary is the testicle, but only when there is disease involvement.[45] The recommended dose for testicular radiation for leukemia is 20 to 24 Gy.

Neuroblastoma

Neuroblastoma is the most common solid non-CNS malignancy and is notable for its diverse behavior, with some cases showing spontaneous regression and others demonstrating dismal outcomes. Radiotherapy is recommended for patients with high-risk disease or sometimes for children with intermediate risk disease progressive after chemotherapy or surgery. The standard dose of radiotherapy recommended to the postchemotherapy presurgical volume is 21.6 Gy.[46,47] For children with residual disease after surgery, a total dose of 36 Gy is recommended to areas of gross disease. Radiotherapy to a dose of 21.6 Gy is also recommended to any metastatic sites that persist after induction chemotherapy. In the setting of multiple metastatic sites still metaiodobenzylguanidine (MIBG) avid after induction chemotherapy, consideration must be given to the amount of tissue to be irradiated. In this situation children are reevaluated after further chemotherapy, and an attempt is made to limit the number of metastatic sites receiving radiation to three. Urgent radiation is sometimes required for respiratory distress as a result of liver metastases in infants. If necessary, a dose of 1.5 Gy for 3 fractions is recommended. Although the radiation dose required to control neuroblastoma is low, these children are typically very young and treatment volumes may be large. Advanced radiation techniques such as IMRT, intraoperative radiation, and proton radiation should be considered.[48-50]

Wilms Tumor and other Renal Malignancies

The North American standard established by the National Wilms Tumor Study (NWTS) and COG cooperative group studies begins with up front surgery followed by radiation if indicated.[51,52] The rationale is to obtain pathology and to surgically define the extent of disease to best determine the appropriate therapy. The International Society of Paediatric Oncology (SIOP) group advises delivering chemotherapy first in attempt to decrease intraoperative tumor spillage. COG radiotherapy guidelines are based on both stage and pathology.[53] Flank radiation is recommended for patients with Stage I to III unfavorable histologies (e.g., diffuse anaplasia, focal anaplasia, clear cell sarcoma of the kidney [CCSK], and CCSK-stages II and III) and for Stage III favorable histology (FH). The standard dose is 10.8 Gy in fractions of 1.8 Gy, but higher doses are recommended for recurrent disease and stage III Diffuse Anaplasia (DA). An additional 10.8 Gy is recommended for any gross residual disease present after resection.[54] Whole abdominal radiotherapy (WART) to a dose of 10.5 Gy at 1.5 Gy per fraction is recommended for positive cytology, diffuse spillage, previous biopsy, or peritoneal seeding. COG guidelines recommend that radiotherapy commence by postoperative day 9 if feasible and no later than postoperative day 14. Whole lung irradiation (WLI) to 12 Gy is recommended for patients with anaplastic disease who have pulmonary metastases at diagnosis or children with favorable histology such as Wilms and pulmonary metastases that fail to respond to initial chemotherapy.[55] Brain, liver, and bone irradiation is indicated when metastases are present.

Rhabdomyosarcoma

Rhabdomyosarcoma (RMS) is the most common soft-tissue sarcoma of childhood and may occur in any location of the body. The COG studies stratify patients into three risk groups (low, intermediate, and high) on the basis of site, stage, histology, and group. Risk stratification is highly complex, but in general risk groups include: 1) low risk: embryonal nonmetastatic favorable sites and embryonal group 1 or 2 unfavorable sites; 2) intermediate risk: embryonal group III unfavorable sites and nonmetastatic alveolar RMS at any site; 3) high-risk: metastatic disease. See Chapter 59 for more details on prognostic factors and risk stratification of RMS.

Combined modality therapy is always used for children with RMS, and this represents another disease site that requires multidisciplinary discussion regarding best management. Radiation treatment depends on several prognostic factors and feasibility of surgery with organ preservation. Surgery is performed up front for resectable tumors and may be attempted after chemotherapy if tumors become resectable, usually with the goal of decreasing radiation dose and sometimes volume.

Contemporary treatment and the existing COG RMS trials require 3D treatment planning to allow full visualization of areas at risk and target volumes. Radiation is omitted only for patients with completely resected favorable histology disease. Thirty-six Gy is recommended for microscopic disease after surgical resection, and nodal disease is treated to a dose of 41.4 Gy. Patients with gross disease receive a dose of 50.4 Gy. Target volumes delineate prechemotherapy volume as the GTV. A margin of 1 cm around this volume to respect anatomic boundaries is recommended to encompass microscopic disease.

Osteosarcoma

Osteosarcoma is the most common primary pediatric bone tumor, but one for which radiation is less often utilized. The use of multiagent chemotherapy has led to a marked improvement in the cure of this disease. Local control is generally achieved with surgery when feasible with reasonable functional outcome. For primary tumors of the base of skull, pelvis, and spine, surgery is not possible and radiation is administered in attempt to achieve local control. Small studies indicate that high radiation doses (50 to 76 Gy) are necessary to provide a reasonable chance of durable local control.[56-60] Proton radiation or brachytherapy may be required to deliver high doses of radiation while limiting the high dose to normal surrounding structures.[56]

Ewing Sarcoma

Ewing sarcoma is the second most common pediatric sarcoma, and multimodality treatment is required. Surgery is again the preferred method of local control if feasible. Primary radiation is indicated for inoperable tumors for which surgical resection cannot be achieved or would lead to major functional impairment.[61,62] Radiotherapy is also indicated for either partially or suboptimally resected tumors. Several studies have helped define recommendations for a radiation dose in the range of 50 to 55.8 Gy to the involved area of bone with a margin for microscopic disease. Most protocols advise that definitive radiation be initiated relatively early, usually by week 12 to 14 of treatment. The initial tumor volume should be treated to a dose of approximately 45 Gy and include all areas of tumor involvement at the time of diagnosis (with adjustments for pushing tumors that have regressed with chemotherapy) and a margin for microscopic disease of approximately 1.5 cm. Gross disease at the time of treatment along with initially involved bone with a margin of approximately 1.5 cm should receive an additional dose of 10.8 Gy to total 55.8 Gy with the exception of tumors located in the vertebral body (total 45 Gy because of spinal cord tolerance).

Retinoblastoma

Retinoblastoma is a rare disease of young children who are almost all under the age of 3 years. Many patients have the hereditary form of retinoblastoma with a high propensity for bilateral disease and subsequent malignancies.[63] Treatment depends on extent of involvement, whether disease is unilateral or bilateral, hereditary status, and sometimes response to treatment and parental preference.[64] Radiation is generally recommended for disease refractory to chemotherapy and local therapies (cryotherapy and laser therapy) in an eye with useful vision, whereas enucleation is advised if it is thought that there is no meaningful visual potential. The standard dose is 45 Gy. Postoperative radiation is delivered for advanced disease after enucleation. A dose of 45 Gy to the orbit and up to the optic chiasm is necessary in cases of frank orbital disease and high-risk pathology features (transscleral extension or tumor involvement of the cut end of the optic nerve). Plaque brachytherapy may be an option for unifocal tumors that are located in the peripheral retina.[65] Radiation does provide an excellent chance at durable control of disease, but carries risks of facial hypoplasia and radiation-induced malignancies.[66] Most data for these toxicities, however, comes from old radiation series with dated techniques as far back as 1914.[67] Modern radiation treatments should maintain disease outcomes while reducing many of these risks. Figure 48-14 depicts a photon radiation plan from 1985 compared to a proton radiation plan from 2012. Given the young age of these children and the propensity of children with hereditary retinoblastoma for second malignancy, proton radiation, which provides the best sparing of involved structures from both high and low doses of radiation, may be the best radiation option for this particular group of patients.

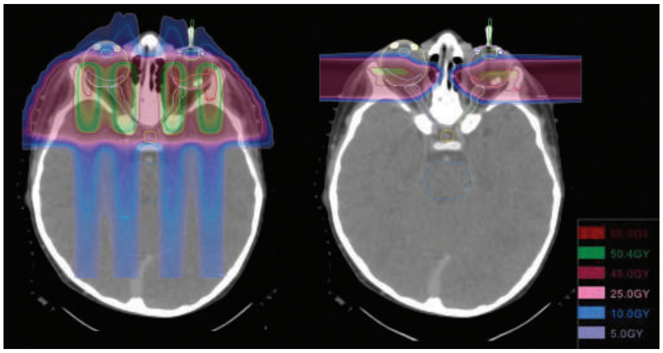

Figure 48-14 Radiation for bilateral retinoblastoma. This figure shows a radiation treatment plan with a 3D conformal photon technique from 1985 *(left)* compared with a modern proton plan from 2012 *(right)*. Protons spare tissues outside of the target volume from low and high doses of radiation. Given that these children are highly vulnerable to second malignancies, avoidance of radiation of any dose is highly desirable.

SEQUELAE OF TREATMENT

Although the goal of therapeutic radiation is to eradicate tumors, tumors are not isolated in petri dishes but occur in the human body in the midst of normal tissues that are susceptible to damage from irradiation. This normal tissue damage occurs during the course of treatment or long after the treatment has been given. The term *acute effects* refers to reactions during or very soon after treatment; reactions occurring more than 3 months after treatment are termed *late effects*. Normal tissue tolerance to fractionated treatment is a function of the volume of the organ or tissue, the total dose, and the time course over which treatment is given. When chemotherapy is given concurrently with radiotherapy, some acute and late toxicities may be enhanced. Acute and late effects are generally restricted to tissues within the radiation field or at least to tissues that received some dose of radiotherapy. The one exception to this is the systemic fatigue, which is experienced by some patients undergoing treatment.

The most typical acute effects are those on skin, on the mucosa of the aerodigestive tract, and on bone marrow. Most acute effects require supportive care, such as topical creams for skin reactions and ongoing hydration, topical anesthetics and in severe cases, narcotics for mucositis. Abdominal irradiation can cause nausea, vomiting, and diarrhea. These toxicities are managed with antiemetics, hydration, and antidiarrheal agents if symptoms are severe. Acute toxicities can be severe and occasionally require treatment breaks. However, prolonged breaks are undesirable, because the overall treatment time is an important factor in tumor control.

The mechanisms of late complications resulting from radiotherapy, though not precisely known, are speculated to be caused by vascular endothelial damage, damage to parenchymal stem cells, or damage to DNA. The normal tissue tolerance doses for the various bodily organs have been well studied.[4] The tolerance doses for adult normal tissue are applied in children with some exceptions, as discussed later. Late effects are dependent on the total dose and fraction size.[68] The potential for late toxicity is one of the most important factors in the decisions regarding dose and volume, and it is a major concern in the treatment of children with cancer.

The late toxicities of radiotherapy are dependent upon both patient factors and treatment factors. The age of the patient, the tolerance of the normal tissue treated, and the dose of the radiotherapy delivered determine the late effects and their severity. Systems most severely affected include the musculoskeletal, endocrine, and reproductive systems, and the CNS.

In children, treatment before full development has been reached can cause abnormal or arrested development. The severity of the effect on musculoskeletal development depends on the dose of irradiation, the area treated, and the age of the patient. Doses of irradiation to the growth plate that are above 20 Gy are likely to have significant effects.[69,70] The age of the patient influences the severity of the damage. Younger children with greater growth potential are more profoundly affected. Irradiation of the pituitary gland and hypothalamus can also lead to short stature by decreasing the production of growth hormone.[71,72] Spinal irradiation in the treatment of medulloblastoma in prepubertal children causes a shortened spine or decreased sitting height.[73,74]

Neurocognitive sequelae from brain irradiation are among the most serious late effects when radiotherapy is used in children.[75,76] The age of the patient, the dose, and the volume of brain treated all influence the severity of these toxicities.[75,77,78] Irradiation of the cochlea can lead to sensory peripheral neuropathy manifested as high-frequency hearing loss.[79] Many children receive ototoxic chemotherapy such as cisplatin, which itself causes hearing loss.[80] When cochlear irradiation is combined with cisplatin, profound hearing loss or sometimes deafness can result.[80]

Germ cell survival in testes and ovaries can be impacted by radiotherapy.[81] Males treated with whole abdominal irradiation may develop gonadal dysfunction. Temporary decreases in sperm count occur in the weeks after low doses of radiotherapy (0.2 to 3 Gy). Recovery occurs in 1 to 3 years, depending on the dose and the age of the patient. Direct testicular irradiation with doses of 24 Gy as used to treat testicular relapses of ALL cause sterility and Leydig cell dysfunction.[82] Total body irradiation combined with cyclophosphamide for stem-cell transplant results in azoospermia for almost all males.[83,84]

Abdominopelvic irradiation in females damages the ovaries resulting in ovarian failure.[85] The incidence of ovarian failure depends upon the age at irradiation and the dose of radiotherapy to the ovaries.[86] When prepubertal girls were treated with WART with 20 to 30 Gy, 71% of girls did not enter puberty and 26% had premature menopause.[86a] CSI with photons can have similar results when treating prepubertal girls, depending upon the dose received by the ovaries.[87]

In addition to organ and system damage, one of the most devastating late effects of radiotherapy is the development of subsequent neoplasms. Survivors of childhood cancer have an increased risk of developing subsequent neoplasms that can be benign or malignant.[88] They can be solid tumors or myelodysplasia/acute myeloid leukemia. Treatment with radiotherapy is associated with the development of subsequent solid tumors.[88] Radiation-associated second tumors occur within the prior radiotherapy field, are of a different histology from the primary tumor, and appear after a latency period of generally at least several years. Several factors are involved in the development of second tumors, including the patient's underlying genetic predisposition, the dose of radiation, and the age and gender of the patient, as well as the specific tissue irradiated.[89] The risk of subsequent radiation-related subsequent neoplasms continues to increase with increased follow-up.[90] This is in contrast to the risk of therapy-related myelodysplasia or acute myeloid leukemia, which plateau after 10 to 15 years.

CONCLUSION

Tremendous improvements have been made in the field of pediatric radiation oncology over the past few decades. Although many children require radiation for curative treatment of their malignancy, treatment can be delivered with fewer side effects. Technological advances allow for more precise delivery of radiation and much better avoidance of healthy tissues outside of the region requiring treatment. Thanks in large part to many cooperative group studies, there is better knowledge of the dose of radiation required to control various tumors. Chemotherapy has allowed for dose reduction for many tumor sites as well as improved outcomes. Pediatric oncologists are beginning to better understand the molecular characteristics and biology of tumors. In the future, this should lead to improved risk stratification, as well as targeted agents to work synergistically with radiation and further improve outcomes for these children.

Technical Considerations

Select Pediatric Malignancies

Successful treatment of pediatric solid tumors requires collaborative management by the disciplines of surgery, oncology, and radiotherapy. Multimodal therapy achieves the highest rate of cure in many solid tumors and often minimizes long-term morbidity. Smooth collaboration provides optimal care. The role of the surgeon varies greatly depending on the primary tumor, its site, and the presence or absence of metastatic disease. Surgeons should be involved in decisions regarding primary resection versus biopsy with neoadjuvant chemotherapy and delayed resection. The surgeon's knowledge of the risks of primary resection is critical; the method of biopsy is also very important. Inappropriate initial excisional biopsies with positive pathologic margins will require more extensive subsequent resection than if an initial incisional biopsy were performed. Similarly, inappropriate biopsies such as thoracoscopic biopsy of a chest wall Ewing sarcoma or a percutaneous or open biopsy of a Wilms tumor needlessly contaminate the thoracic and abdominal cavities, respectively, and require more intensive therapies, particularly the use of radiation therapy. A growing emphasis on minimizing the morbidity of therapy is required, because the survival for infants and children with many solid tumors is quite high. It is important, therefore, to avoid any diagnostic or therapeutic missteps that require more intensive therapy.

Surgery is critical in the staging of pediatric solid tumors. This is well established in Wilms tumor. In a classic study by Beimann Othersen and the National Wilms Tumor Study Group (NWTSG), surgeons had a 31.3% false-negative rate in their clinical assessment of lymph-node involvement with tumor by gross inspection and a false-positive rate of 18.1%.[1] It should be stressed that in Wilms tumor the protocols of the NWTSG and the Children's Oncology Group (COG) determine the intensity of chemotherapy as well as whether or not abdominal radiotherapy is utilized. Patients with pulmonary metastases (stage IV) with local stage I or stage II tumors receive intensified chemotherapy and pulmonary radiation but no abdominal radiation.

The vital importance of adequate lymph-node biopsy has been demonstrated in several studies. An increased incidence of local relapse occurred in children enrolled in the NWTSG-4 study if no biopsy was performed of the abdominal lymph nodes, particularly in stage-I cases.[2] This finding suggests that inadequate treatment of local disease in children without lymph-node biopsy results in an increased rate of local relapse. Although lymph-node biopsy is essential in children with Wilms tumor, an extensive retroperitoneal lymph-node resection has not been demonstrated to improve local control.[3]

Lymph-node biopsy in patients with rhabdomyosarcoma is critical as well. The incidence of lymph-node involvement in rhabdomyosarcoma is determined by the primary site. Children without evidence of distant metastases have an overall 10% incidence of lymph-node involvement. It is most common in tumors arising in the prostate (41%), paratesticular (26%), and genitourinary sites (24%).[4] Lesions in the extremities have an intermediate rate of 12%, whereas the orbit (0%), truncal sites (3%), and nonorbital head and neck (7%) have the lowest rate of lymphatic dissemination. In the extremity and genitourinary sites, assessment of lymph-node involvement is essential to ensure that radiation fields are appropriately designed and sufficiently inclusive. Whether the sentinel lymph-node biopsy technique optimizes the identification of nodal spread in rhabdomyosarcoma has not been established, but it has been reported to be feasible in pediatric patients with minimal morbidity.[5] Although lymph-node biopsy is critical to identify the extent of spread, a lymph-node dissection should generally not be performed, because it may produce lymphedema that complicates radiotherapy and subsequent surgical resection of the primary tumor.

Radiographic assessment is inadequate for staging rhabdomyosarcoma as it is in Wilms tumor. In the Intergroup Rhabdomyosarcoma Study III (IRS-III), 121 boys with paratesticular rhabdomyosarcoma had a retroperitoneal lymph-node dissection to evaluate nodal status.[6] The lymph nodes were assessed to be clinically negative based on computed tomography (CT) scan in 18% of the boys, 14% of whom had positive nodes when biopsy or retroperitoneal lymph-node dissection was performed. In the boys with clinically positive lymph nodes based on the CT scans, 94% were confirmed to be positive pathologically. Retroperitoneal relapse occurred in only two of the 121 boys, one of whom had pathologically negative lymph nodes and did not receive radiotherapy. Thus CT was very accurate if lymph-node abnormalities were identified, but it was not extremely sensitive in identifying nodal involvement. In a subsequent study, Weiner and colleagues reported an increased incidence of retroperitoneal relapse in children treated during IRS-IV. The use of abdominal radiation in this study was based on thin-cut CT scans in 98% of cases as compared with children treated during the preceding IRS-III, in which 94% had retroperitoneal biopsy or lymph-node dissection. In the subsequent study, IRS-IV, a decrease in stage-2 disease (positive lymph nodes) from 35% to 17% occurred when the staging was based on radiographic findings. This resulted in a decrease in the use of abdominal radiation in this cohort. The result was a fourfold increase in retroperitoneal lymph-node relapse. Another example of how critical adequate staging is to avoid local failure.[7]

This chapter discusses some of the critical surgical issues in the treatment of infants, children, and adolescents with solid tumors. The use of anesthesia in patients with an anterior mediastinal mass, appropriate methods of biopsy, the role of neoadjuvant chemotherapy, limb salvage procedures for osseous tumors, and the management of pulmonary metastases are addressed.

ANESTHESIA IN PATIENTS WITH AN ANTERIOR MEDIASTINAL MASS

Patients presenting with an anterior mediastinal mass pose a therapeutic challenge to the anesthesiologist and the surgeon. Correct diagnosis of the tumor provides the greatest chance of cure. There are, however, a plethora of reports in the anesthesia and surgical literature of patients with an anterior mediastinal mass suffering respiratory collapse upon the induction of general anesthesia. This occurrence has led to an understandable reluctance among anesthesiologists to use general anesthesia in this setting. Respiratory symptoms are a poor index of the risk of respiratory collapse, with the clear exception of orthopnea, which suggests a high risk that respiratory collapse will occur. An initial attempt to establish the radiographic parameters that would correlate with respiratory collapse upon induction of general anesthesia involved a retrospective evaluation of 74 adults with Hodgkin disease.[8] In this study, the authors used the ratio of the transverse diameter of the mediastinal mass and the transverse diameter of the chest as the critical parameter. They found the incidence of respiratory collapse was 2.1% with a mediastinal mass less than 31% of the transverse diameter, compared with 10.5% for a mass with a ratio of 32% to 44% and 33.3% for a mass with a ratio greater than 45%. Similar results were reported by Turoff and associates.[9]

Thorne Griscom and colleagues demonstrated that CT scan can accurately determine the tracheal dimensions in children and adolescents, and he established the normative values in children.[10-12] Azizkhan first used this methodology in reviewing 50 children with anterior mediastinal masses. He found that 15 patients in his cohort had "marked" tracheal compression that was defined as a tracheal cross-sectional area less than 66% of predicted. When general anesthesia was induced in eight of these 13 patients, total airway obstruction occurred in five, all of whom had 50% or less of the predicted tracheal area. It was suggested, based on these findings, that general anesthesia should be avoided in children with less than 66% of the predicted tracheal area.

In a retrospective study at Boston Children's Hospital, 42 patients were identified who had an anterior mediastinal mass and a CT scan and underwent a surgical procedure. These patients were divided into those with tracheal area greater than 75% of expected (19 cases), those with 50% to 75% predicted area (16 cases), those with 25% to 50% (5 cases), and those with less than 25% (2 cases).[13] One clear finding of that study was that the presence or absence of respiratory symptoms did not correlate well with the degree of tracheal narrowing shown by CT scan, except for orthopnea (Fig. 49-1). General anesthesia with spontaneous ventilation was performed in four patients (with tracheal areas 33%, 73%, 76%, and 98% of predicted). General endotracheal anesthesia with paralysis was used in the remaining 32 patients, only three of whom had tracheal area of less than 50% of

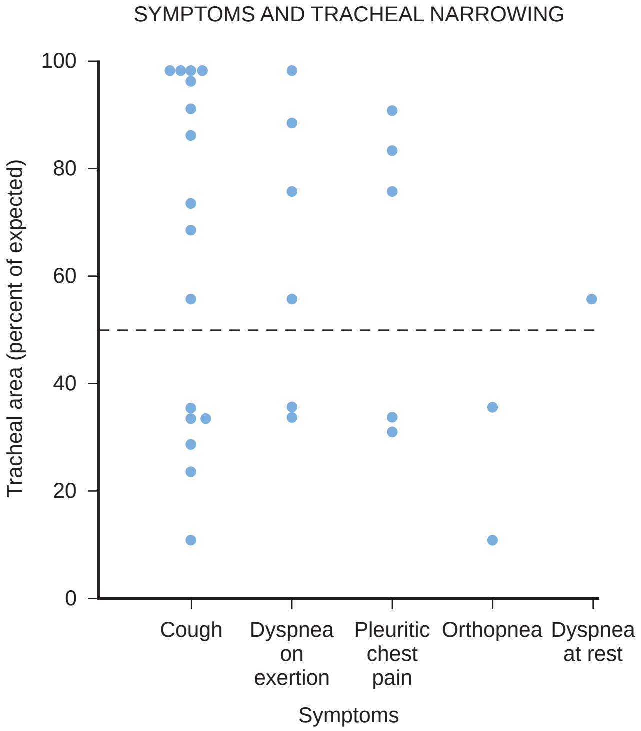

Figure 49-1 Correlation of symptoms with tracheal areas is shown for a cohort of 42 children and adolescents with an anterior mediastinal mass. *(Modified from Shamberger RC, Holtzman RS, Griscom NT et al: CT quantitation of tracheal cross sectional areas as a guide to the surgical anesthetic management of children with anterior mediastinal mass.* J Pediatr Surg *26:138–142, 1991.)*

predicted (30%, 26%, and 24%). One patient received preoperative radiation therapy (26%). None of these 32 patients had symptoms of orthopnea or dyspnea at rest, and only one had dyspnea on exertion. All tolerated anesthesia without difficulty, and no patients suffered respiratory or cardiovascular collapse. Adequate material for pathologic diagnosis was obtained in all cases. It was concluded in this study that general anesthesia was safe in patients with tracheal areas greater than or equal to 50% of predicted.

In a subsequent prospective study, 31 children with a mediastinal mass were evaluated with both CT scan and pulmonary function tests.[14] Although the use of pulmonary function tests had been proposed by multiple investigators as a method to assess anesthetic risk, little evaluation of this modality had been performed. Miller and Hyatt evaluated the flow volume loop curves in a series of patients with intrathoracic and extrathoracic obstruction resulting from strictures of the trachea, malignant tumors, or bilateral vocal cord paralysis.[15] The predominant distortion of the flow loops for intrathoracic obstruction was a marked reduction in the maximum expiratory flow rate. Hence in this prospective study, the peak expiratory flow rate was used as a critical factor. Patients with either a peak expiratory flow rate of less than 50% of predicted or a tracheal area of less than 50% of predicted had local anesthesia for their procedures. General endotracheal anesthesia was used only in patients with greater than 50% of predicted for both parameters. All patients in this study did well when general anesthesia was applied (Fig. 49-2). Further analysis of this cohort revealed that patients with a tracheal area greater than 50% but a peak expiratory flow rate (PEFR) less than 50% had one of two problems: either a very low total lung capacity (38% and 55% of predicted) resulting from the massive size of the tumor or moderate to severe bronchial narrowing by qualitative estimation (four of these five patients) (Fig. 49-3).

In a subsequent study by King and coauthors, 51 children with Hodgkin lymphoma and non-Hodgkin lymphoma (NHL) were evaluated. Respiratory symptoms were present in 49% of the children in this series and were more prevalent in children with non-Hodgkin lymphoma (76%) than in those with Hodgkin lymphoma (30%). The extent of aberration in the pulmonary function test was also worse in those with non-Hodgkin lymphoma. The first-second forced expiratory volume (FEV$_1$) was more affected in the group with NHL (mean value of 63 +/– 27% of predicted) compared with the children with Hodgkin lymphoma (mean value of 87 +/– 16% of predicted).

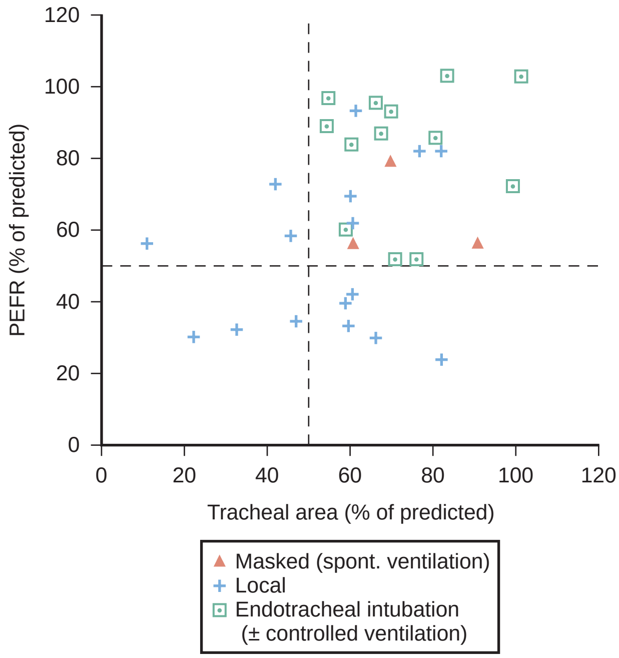

Figure 49-2 This figure shows the relationship between peak expiratory flow rate (PEFR) and tracheal area in a cohort of 31 children prospectively evaluated with an anterior mediastinal mass. Children with PEFR and/or tracheal area less than 50% of predicted (below or to the left of the *dotted lines*) all received local anesthetic and did well. Those children with PEFR and tracheal area greater than 50% of predicted received predominantly general anesthesia and did well *(right upper quadrant)*. The five children with tracheal areas greater than 50% of predicted but with peak PEFR less than 50% of predicted (in *lower right box*) might have been considered for general anesthesia if the tracheal area was the only parameter considered in assessing risk. Although the study could not demonstrate that these children would have had anesthetic problems, it did confirm that the parameters of greater than 50% PEFR and tracheal areas greater than 50% of predicted were safe for the administration of general anesthesia. *(Modified from Shamberger RC, Holzman RS, Griscom NT et al: Prospective evaluation of computed tomography and pulmonary function tests of children with mediastinal masses.* Surgery *118:468–471, 1995.)*

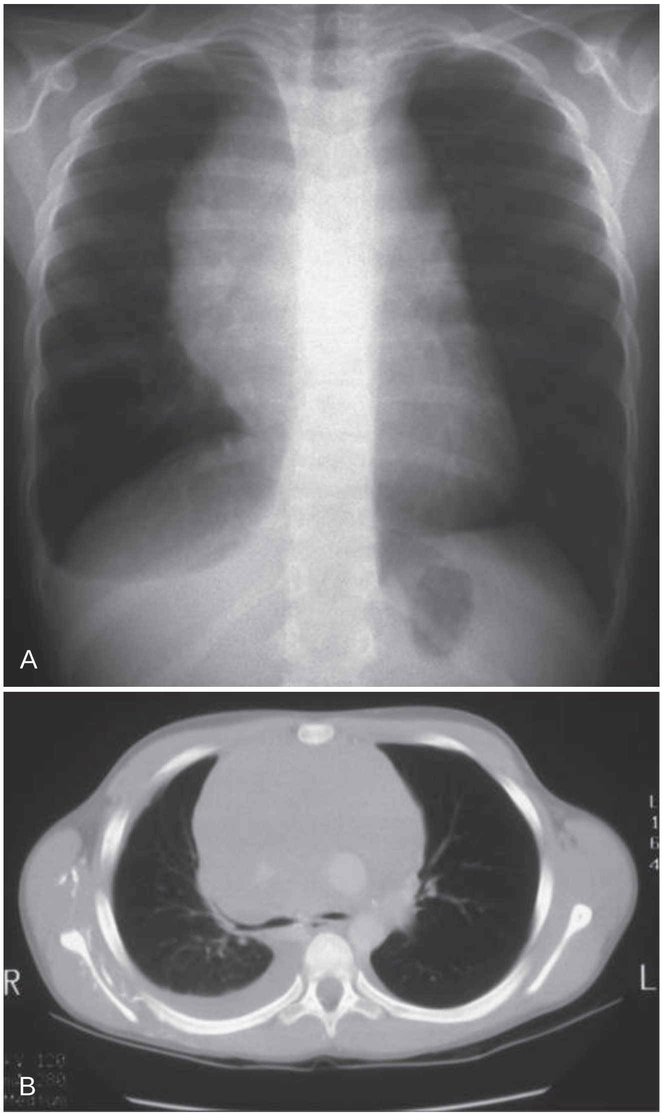

Figure 49-3 Chest imaging of an 11-year-old female who had a several-week history of a cough and dyspnea on exertion, as well as puffy eyes and orthopnea. The radiograph (**A**) reveals an anterior mediastinal mass, and a CT scan (**B**) shows a tracheal area that was 82% of predicted but revealed marked narrowing of the bronchi. The patient's peak expiratory flow rate was only 42% of predicted while sitting and 24% of predicted while supine. Aspiration of her pleural effusion confirmed the diagnosis of lymphoblastic lymphoma. *(From Shamberger RC: Preanesthetic evaluation of children with anterior mediastinal masses.* Semin Pediatr Surg *8:61–68, 1999.)*

Patients with severe obstruction have one of three therapeutic options available. Patients can be treated in a preliminary fashion with either radiation therapy or steroids/chemotherapy for the most likely diagnosis based on the clinical findings (Fig. 49-4). In a series of young adults who underwent a postradiation biopsy of an anterior mediastinal mass, a histologic diagnosis could not be obtained in eight of 10 patients because of extensive necrosis.[16] In some cases, one area of tumor can be shielded for subsequent biopsy while the bulk of the tumor receives radiation. Non-Hodgkin lymphoma (NHL) is also extremely responsive to steroid therapy. Pretreatment with steroids also often obscures the histologic diagnosis.[17,18]

The second option is aspiration of a pleural effusion if present. Patients with lymphoblastic lymphoma have a higher incidence of an associated pleural effusion (71%) than children with Hodgkin lymphoma (11.4%).[19] Aspiration of the effusion in patients with lymphoblastic lymphoma is often diagnostic. Cells in the effusion can be assayed by immunocytochemical studies as well

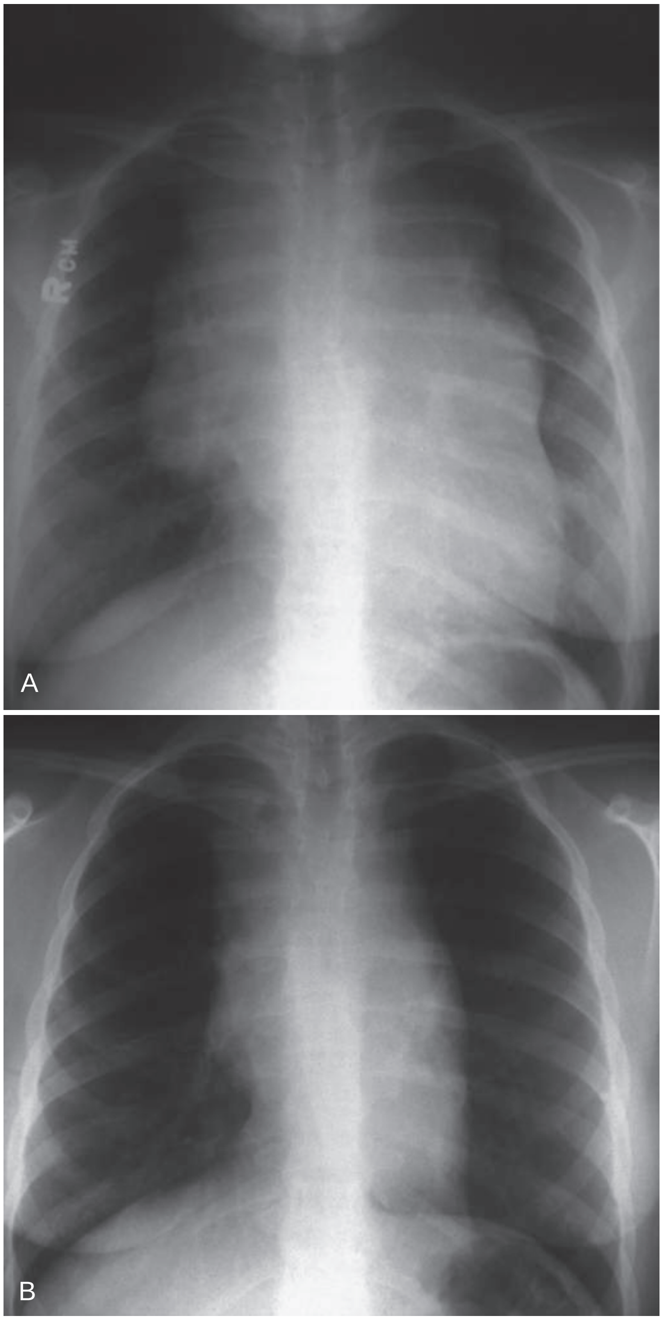

Figure 49-4 A 14-year-old girl with a nonproductive cough, retrosternal pain, 19-pound weight loss, and orthopnea. **A**, The chest radiograph showed a large anterior mediastinal mass. A biopsy was obtained in the suprasternal notch revealing lymphoblastic lymphoma. She received two courses of radiotherapy (250 cGy/per dose) over 2 days. Her chest radiograph obtained 7 days later (**B**) showed a remarkable response of the tumor to the radiation. *(From Shamberger RC: Preanesthetic evaluation of children with anterior mediastinal masses.* Semin Pediatr Surg *8:61–68, 1999.)*

as by cytogenetic evaluation, immunophenotyping, and cytology.

Third, in children with significant respiratory compromise and no pleural effusion and no lymph nodes palpable outside the chest, either a percutaneous needle biopsy under radiographic guidance or an open anterior thoracotomy (Chamberlin procedure) can be performed successfully when the child is under local anesthesia. Children should be seated in a semiupright position and spontaneously ventilating to maximize their pulmonary function (Fig. 49-5). This position also decreases venous congestion if it is present. Spontaneous ventilation minimizes collapse of the trachea by the negative pressure exerted by the chest wall. It has also been shown that in children, image-guided percutaneous needle biopsy can in most instances provide a diagnosis.[20] The major challenges have been in children with Hodgkin lymphoma, where initial biopsy was able to provide a conclusive diagnosis in only 50% of the children (six of 12). An algorithm for safe management of these children and adolescents is shown in Figure 49-6.[21] Following these

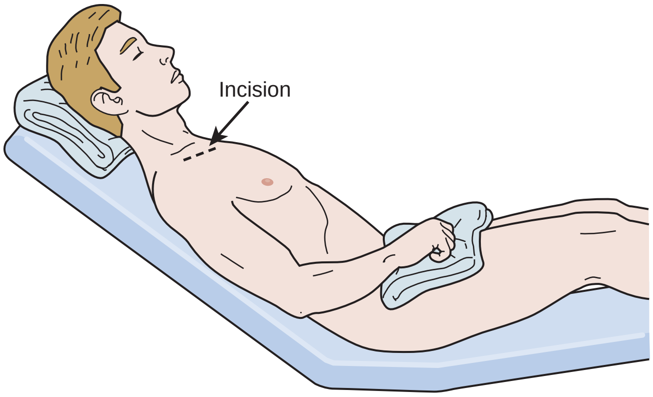

Figure 49-5 Proper position for patient with airway compromise to obtain a biopsy of an anterior mediastinal mass. The upright position optimizes pulmonary function and facilitates ventilation as well as venous drainage from potentially engorged vessels. *(From Shamberger RC: Preanesthetic evaluation of children with anterior mediastinal masses.* Semin Pediatr Surg *8:61–68, 1999.)*

guidelines for the use of general and local anesthesia and the biopsy techniques discussed, a biopsy can be obtained safely in essentially all children and adolescents with an anterior mediastinal mass.

METHODS OF BIOPSY

A biopsy serves as the basis of diagnosis and treatment of a tumor. It will establish the prognosis and define the multimodality therapy required for cure. Beyond establishing the diagnosis, a biopsy may be required for several other important purposes in the delivery of modern oncological care: to confirm the presence of metastatic disease; to determine the response to treatment; and to document the presence of complications from treatment, especially suspicious lesions that may be infectious in nature and pose a significant risk to a patient with immunosuppression.

The Five Principles

Five principles must be followed when considering a biopsy. First, to minimize the psychological and physical stress for the patient and family, the need for a biopsy, how it will be performed, and the possible complications must be discussed with the patient and family.

Second, a preprocedure conference between the oncologist, pathologist, radiologist, and surgeon must ensue to determine the best biopsy technique to obtain the required amount of tissue and that the tissue is processed appropriately (light microscopy, electron microscopy, cytogenetic and other biogenic marker evaluation, and immunohistochemical analysis) to provide the maximum information.

Third, the precise biopsy route and site must be selected to facilitate future therapy. The wrong incision or biopsy site can greatly complicate the subsequent “local” therapy, whether it be resection or radiotherapy. Factors that must be considered are local tissue trauma, risk of tumor spillage or hemorrhage, and minimal violation of anatomic planes.

Fourth, the patient’s general state of health, past medical history, and immune status must also be considered to fully assess the physiologic impact of anesthesia and biopsy, including risk of hemorrhagic and respiratory collapse.

Lastly, the possibility of combining several invasive procedures into one anesthetic should be considered. For example, a patient that requires a biopsy of a lesion may also need central venous access or a bone marrow biopsy and aspirate, and these procedures could all be combined. Although the grouping of procedures is not always possible, it is an option that the oncologic team needs to discuss in advance and then present a uniform plan to the patient and parents.

Method of Biopsy Overview

The type of biopsy a patient requires varies greatly and is dependent upon the site of the mass, the characteristics of the lesion itself (cystic or solid), the condition of the patient, and the diagnostic possibilities. Once the decision has been made to proceed with a biopsy, the first technical question that must be answered is the amount of tissue required and what biopsy technique will avoid increasing the stage of the patient or complicate future therapy. The fundamental separation of techniques is into small- or large-specimen biopsies.

Small-Specimen Biopsies

Small-specimen biopsies are those that are acquired through the use of hollow needles that sample an aspirate (fine needle aspiration [FNA]) or core (core needle biopsy [CNB]) of the tissue. They are often obtained with imaging assistance (ultrasound, fluoroscopy, or CT). The advantages of small-specimen biopsies are that they can often be performed with minimal or no anesthesia and are less invasive than an open procedure. Cost is also generally less for this approach, and recovery time for the patient is quicker. The disadvantages to this approach, however, are that the amount of tissue returned is quite small, which may create challenges in establishing a diagnosis or may not provide adequate tissue to complete the necessary secondary tests to adequately define the lesion. Furthermore, if imaging modalities are used to assist in this form of biopsy, then radiation exposure will occur if CT or fluoroscopy is used as opposed to magnetic resonance imaging (MRI) or ultrasound. This issue of radiation exposure is of extreme importance in the pediatric population, because there is an increased risk of developing a malignancy from radiation exposure.[22,23] In addition, there is the possibility of tumor spread in needle tracts or hemorrhage.[24-26] The risk of sampling error in which the specimen harvested may not adequately represent the entirety of the mass is always a concern with biopsies, and the smaller the sample, the larger the concern. Despite these limitations, small-specimen biopsies are an accepted standard of practice in pediatric oncology, and their use will be described in detail in the following section.

Fine Needle Aspiration and Core Needle Biopsy. FNA specimens are acquired by using a 20- to 25-gauge needle connected to a standard syringe with the plunge partially withdrawn (Fig. 49-7). The needle is inserted directly into the lesion guided by palpation or with image guidance (Fig. 49-8). Multiple passes are taken from the lesion as suction is applied to the syringe. Upon removing the needle, the contents of the syringe and needle are placed directly onto slides for cytological analysis. Multiple biopsies (3 on average) can be taken with this approach from the same lesion at the same time, and the cytological

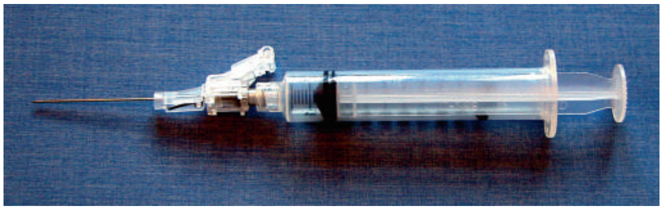

Figure 49-7 This figure shows a standard fine needle aspiration device with a 22-gauge needle attached to a 10-cc syringe that has the plunger partially withdrawn to facilitate the removal of the aspirate.

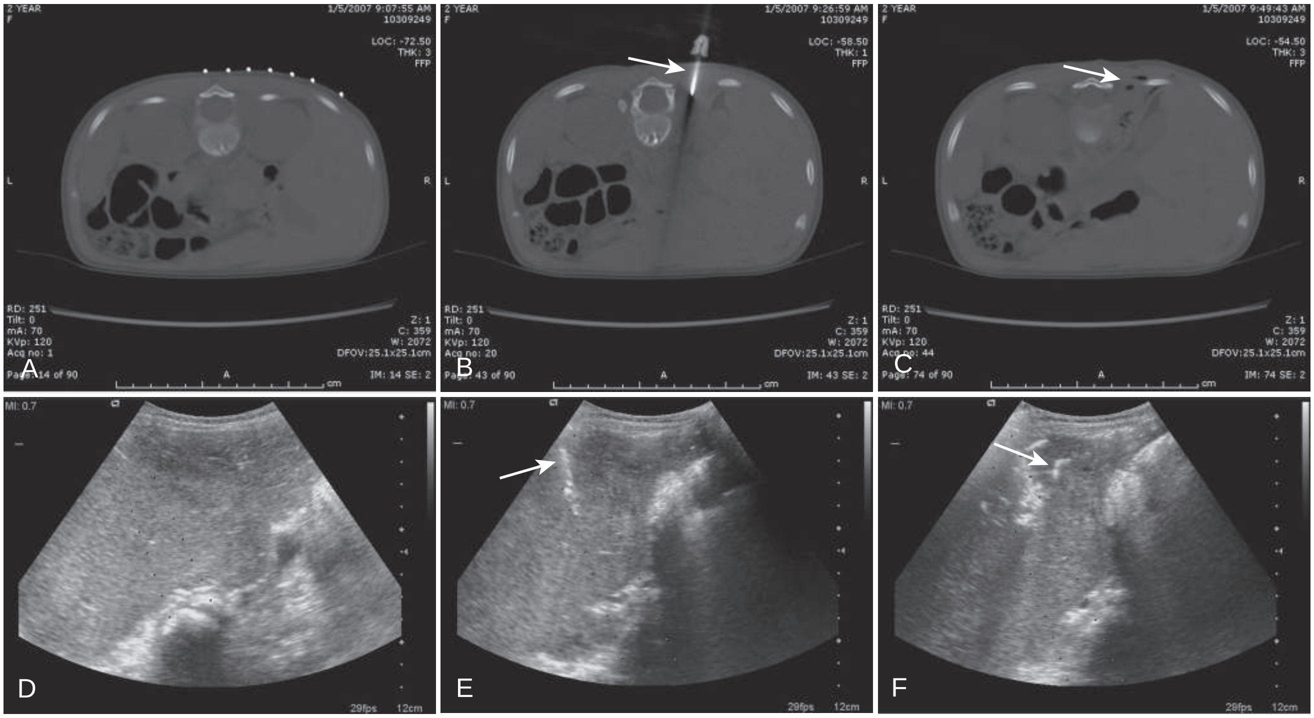

Figure 49-8 **A**, Prebiopsy computed tomography (CT) of a retroperitoneal mass with external grid for biopsy marking. **B**, The same patient with the needle in the retroperitoneal mass *(arrow)*. **C**, Postbiopsy CT with air in the mass and soft tissues *(arrow)* from the biopsy procedure. **D**, Prebiopsy ultrasound of a liver mass. **E**, Ultrasound-guided biopsy of a liver mass *(arrow)*. **F**, Postbiopsy hemorrhage in the mass is depicted *(arrow)*.

results are available for almost immediate review. However, no histologic assessment is possible using this technique, thus causing difficulty in diagnosing certain tumors with cytologic appearances that are quite similar, such as the small, round, blue cell tumors.

Histopathologic analysis is possible with a CNB. CNB specimens are retrieved using larger, hollow-bore needles (13- to 20-gauge) attached to spring-loaded devices that allow for one-step tissue harvest and extraction (Fig. 49-9). Image guidance is often used during this procedure, just as it is for the acquisition of FNA samples. The CNB device is often inserted through a coaxial sheath or cylinder that allows the operator to instill a coagulant into the tissue defects made by the CNB device to reduce the incidence of hemorrhage and tumor spillage (Fig. 49-10). Generally multiple specimens (10 or more) from different areas of the lesion are gathered with this technique to minimize sampling error and to provide more tissue for complete pathological analysis.[27-29] A representative example of the microscopic appearance of the biopsy specimens for FNA and CNB is shown in Fig. 49-11. Imaging techniques can often distinguish areas with viable versus necrotic tissue to help identify the area best to biopsy.

The results and outcomes of small-specimen biopsies from almost any organ in the body have been reported extensively in adult patients with excellent diagnostic accuracy and minimal procedural morbidity. However, small-specimen biopsy techniques and comparison of these techniques in pediatric oncology patients, especially with abdominal lesions, have only recently gained widespread acceptance and usage.[29-35]

Hugosson and colleagues in 1999 reviewed their series of image-guided percutaneous small-specimen biopsies in children from 1992 through 1996.[31] A total of 90 biopsies (53 FNA, 37 CNB) were taken in 75 patients (mean age of 6.9 years). They compared the use of FNA with CNB (1.2 mm core specimens) under ultrasound guidance. Their cohort had many different malignant

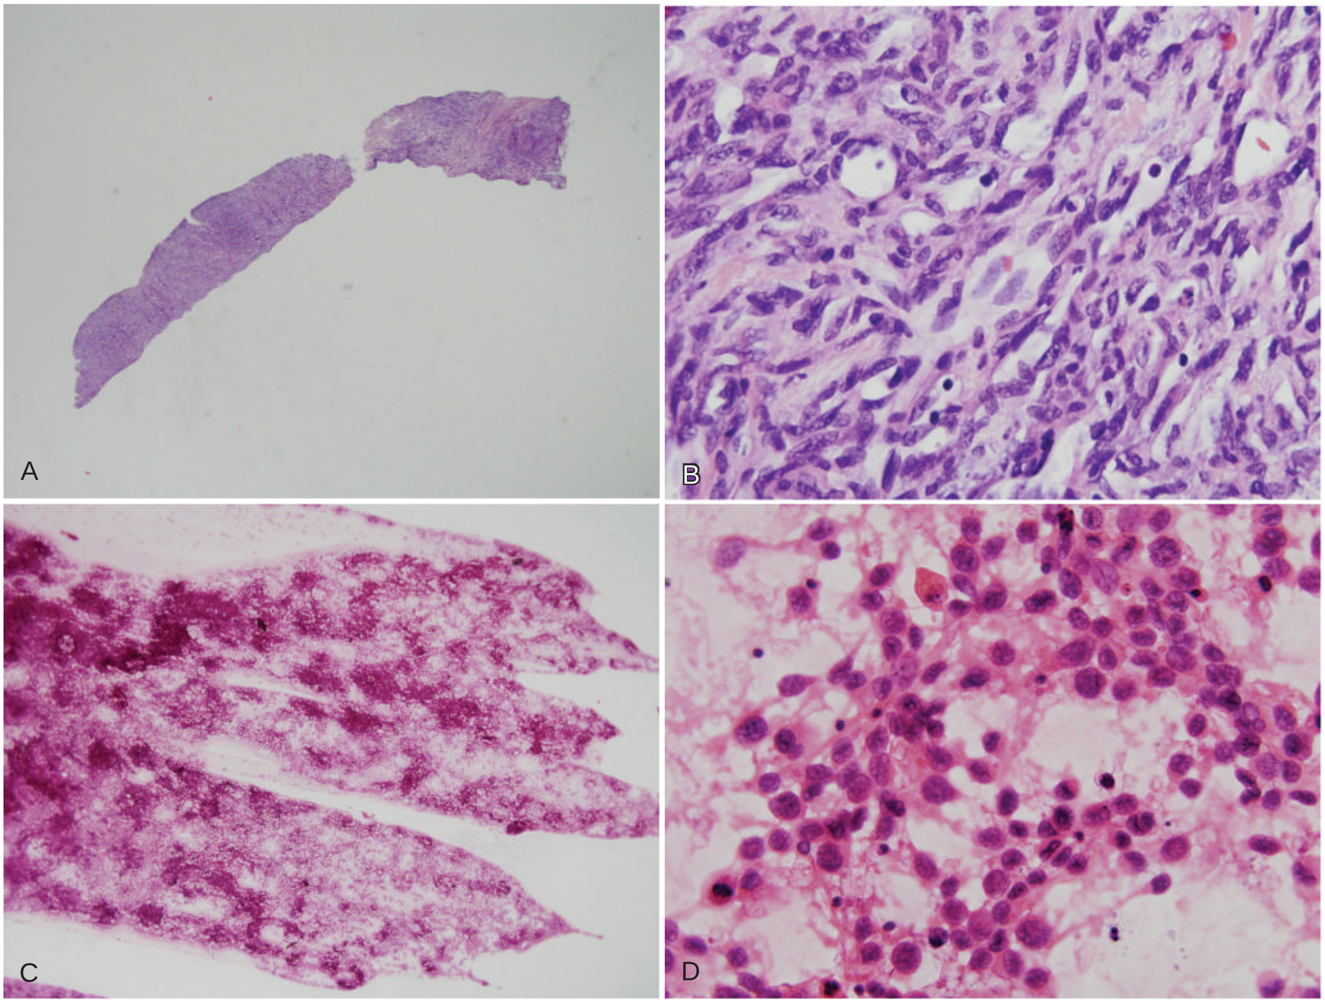

Figure 49-11 **A**, Core needle biopsy specimen from a liver mass at ×2 (angiosarcoma). **B**, CNB at ×600 with sheets of moderately pleomorphic spindled cells and lumina formation. **C**, Fine needle aspiration specimen from a submandibular lymph node at ×2 (nasopharyngeal alveolar rhabdomyosarcoma). **D**, Specimen at ×600 revealing round and elongated pleomorphic tumor cells with marked apoptosis.

processes, and they obtained biopsies from the liver, kidney, adrenal gland, spleen, pelvic masses, and enlarged abdominal lymph nodes. Their FNA diagnostic accuracy was 77% (73% for malignant lesions and 83% for benign lesions) and 95% for CNB (93% malignant lesions and 100% for benign lesions). The complication rate was 8%. They concluded that CNB is a more accurate technique with a similar complication rate to FNA. These results were echoed by Hussain and colleagues, who examined their institutional experience on image-guided percutaneous biopsies (using CNB) in children (mean age, 4 years-old).[32] Ninety-four percent of their cohort had abdominal or pelvic masses. Their reported diagnostic accuracy was 88%, and the initial diagnosis was subsequently confirmed by whole-specimen pathologic analysis. Their complication rate was approximately 8%, and they also concluded that CNB was generally successful in diagnosing tumors in children.

Sklair-Levy and colleagues published their institution's 10-year experience in small-specimen biopsies on pediatric patients.[33] They performed 69 (62 CNB) biopsies in 57 patients using image guidance. Their diagnostic accuracy was 88.7% (55 of 62 patients). For malignant lesions, CNB had an accuracy of 98% as an isolated diagnostic technique in solid malignant tumors, although seven CNBs had to be repeated because the initial results were nondiagnostic. All seven repeated CNBs were correct on subsequent evaluation. They performed seven FNAs with a diagnostic accuracy of only 28%, and these patients then underwent surgical excision of the lesion in question. Although this accuracy rate is far lower than previously reported,[31] none of the lesions in question were abdominal or pelvic masses, and the majority of these lesions were enlarged lymph nodes. Therefore direct comparison of the utility and diagnostic accuracy of FNA in this situation is not possible. Their accuracy with primary, metastatic, or recurrent lesions was in excess of 94% for all tumor types except lymphomas, for which they were correct only 60% of the time. Interestingly, they did not have a single complication.

A more comprehensive study was published by Skoldenberg and colleagues. They examined their institution's results with 147 CNBs in 110 children (mean age 4 years) from all anatomic sites (61 abdominal and pelvic lesions of the total 110 children).[34] An overall accuracy of 89% was achieved for the CNBs performed. Twenty-four children required 37 additional biopsies for a nondiagnostic first specimen (12), a question of recurrence (22), and an insufficient quantity of tissue for all the diagnostic studies needed (3). They reported a sensitivity of 82% and a positive predictive value of 98.8%. A complication rate of 7% (10 of 141 cases) was seen, of which half were hemorrhagic in nature. Fourteen of the patients required narcotics for pain management postprocedure. A statistically significant difference in the occurrence of postprocedure pain was noted in older children. The authors strongly encourage the use of CNB in the diagnosis of pediatric malignancy, and they tout its superiority to FNA.

St. Jude's Children's Research Hospital published their experience of CNB in pediatric solid tumors over 5 years.[30] Two hundred and two CNBs were performed using image guidance and anesthesia. Ultrasound was the predominant mode of imaging assistance (124 of 202), and the biopsies were performed to evaluate both primary and metastatic sites of disease. One hundred and three primary CNBs were performed with a 96.9% sensitivity, a 100% specificity, and an accuracy of 98%. For metastatic or recurrent lesions, they measured a sensitivity of 83.1%, a specificity of 100%, and an accuracy of 87.9%. There were no false positive results. In the cohort of patients with abdominal and pelvic tumors, the sensitivity and accuracy of CNB was 100%. They had a complication rate of 13.4%, with hemorrhage being the most common. Their results and experience across all anatomic regions and pathologic lesions demonstrate that small-specimen biopsies should be considered the initial diagnostic procedure of choice. Therefore solid masses in the pediatric population should be approached where indicated with image-guided small-specimen biopsies, especially using the CNB technique.

Finally, Sebire and Roebuck[36] reported the results from a systematic literature review they conducted to determine the utility, success, and complications from image-guided CNBs. Echoing similar studies, they report that 94% of all procedures obtained adequate tissue for evaluation, and of that group an accurate diagnosis by histopathologic analysis was achieved in 94% with only a 1% complication rate.

Large-Specimen Biopsies

Large-specimen tissue biopsies involve the removal of all (excisional) or part (incisional) of a lesion using an open or minimally invasive surgery (MIS) technique. This method of biopsy should not be confused with a formal extirpative procedure, because the surgeon does not remove either part or all of the entire mass with concerns about adequate margins of resection. The goal of these procedures is to remove a piece or all of the mass in question to provide tissue for a diagnosis, not for local control of the primary site. Large-specimen biopsies are also performed in anatomic areas or on lesions where image-guided small-specimen biopsies are more difficult because of proximity to major vessels or nerves, the lesions are very vascular, or the lesions cannot be reached without damaging overlying organs and structures (i.e., retroperitoneal lymph nodes). Large-specimen biopsies may be performed sequentially with a small-specimen biopsy using the same anesthetic if there is any doubt regarding the adequacy for a histopathologic diagnosis of the FNA or CNB.

Several disadvantages of large-specimen biopsies are a longer procedural and anesthetic time, recovery time, and need for hospitalization. They can delay the initiation of adjuvant therapies and are more costly. Assuming there are no complications, the vast majority of pediatric patients who have a small-specimen biopsy performed on a solid abdominal mass do not stay more than 8 hours postprocedure, as evidenced in recent large studies.[30,32-35,37] The same cannot be said for large-specimen biopsies. Finally, operative exploration for large-specimen sampling can complicate definitive local-control therapies, especially from an operative standpoint. Violating the thoracic or peritoneal cavities induces adhesion formation that can complicate the subsequent resection.

Although significant disadvantages to large specimen biopsies exist, there are marked advantages. First, large biopsy samples are obtained, and multiple areas are sampled within the lesion, decreasing the likelihood of sampling error. Second, a detailed macroscopic evaluation of the lesion in question and all surrounding structures can be performed to search for extension or metastasis from the tumor. Third, radiation exposure is avoided for the patient and the healthcare team. Finally, hemostasis and tumor sampling is controlled and confirmed directly before closing the incision to minimize the complications of tumor spillage and hemorrhage.

In the last decade, several groups have reported success using a MIS approach for either incisional or excisional large specimen biopsies. The MIS approach relies on the same basic tenets of surgical discipline as does an open procedure, but it uses smaller incisions and advanced technology to achieve these goals. An operating telescope capable of excellent image resolution and magnification is used to display a picture on closed-circuit monitors. Dissection and biopsy is performed with long, fine instruments introduced through a percutaneously placed 2- to 12-mm canula. When operating in the peritoneal cavity, carbon dioxide gas (CO_2) is introduced by an insufflation apparatus that distends the abdominal wall to provide adequate space to assess the abdominal structures. The pressure is kept as low as possible, consistent with adequate exposure. An important point that must be discussed with the anesthesiologist is the degree of respiratory impairment that CO_2 insufflation may induce, especially in pediatric patients with extremely compliant diaphragms. If at any point the child becomes physiologically unstable, the CO_2 gas is released and the procedure is terminated. Advantages of the MIS approach are decreased postoperative pain from the small incisions, a shorter postoperative stay, improved cosmetic results, and an earlier return of bowel function.[35,38] A complication rate in the pediatric population of 4% or less has been reported in a recent large series, but this rate is clearly related to the experience of the surgeon.[38]

In 1973 Gans and Berci described their successful experiences with MIS in pediatric patients, but their procedures were not related to tumors.[39] In fact, it was not until Holcomb and colleagues' report from the Surgical Discipline Committee of the Children's Cancer Group (CCG) in 1995 that the MIS approach was formally reviewed for its efficacy in oncology.[40] In this study from 15 participating centers, 25 abdominal and 63 thoracic explorations were undertaken for the purposes of diagnosis (primary, relapsed, and metastatic lesions), staging, assessment of resectability, and the evaluation of treatment complications. All abdominal lesions (16), and 50 of 51 thoracic lesions that required biopsy were successfully diagnosed. There were no perioperative mortalities, and only seven complications—all in the thoracic cohort.

A prospective trial sponsored by the National Institutes of Health (NIH) concerning the use of MIS in pediatric oncology patients was begun by the combined Surgical Discipline Committees of the CCG and the Pediatric Oncology Group (POG) in 1996.[40] The study failed for lack of accrual, and it was closed after 2 years. A questionnaire soliciting reasons for the failure of this study documented that lack of familiarity with the MIS technique by both the surgeon and the institution, surgeon and pediatric oncologist bias against the MIS technique, and the failure to submit the necessary paperwork to local institutional review boards for study approval were statistically significant factors in the study's failure. Despite these results, MIS is gaining acceptance in pediatric oncology, especially for the diagnosis of lesions.

Spurbeck and colleagues at the St. Jude's Children's Research Hospital recently published their experience with MIS in pediatric oncology patients from 1995 through 2000.[41] One hundred and one patients underwent 113 operations (64 abdominal and 49 thoracic procedures). Abdominal biopsies were attempted in 25 patients and were successful in 23 (92%). Evaluation of resectability was determined successfully in two other cases, and seven extirpative procedures were performed. There were three complications in the abdominal group, and four MIS procedures were converted to open procedures. There were three complications reported in the abdominal cohort. The thoracoscopic procedures had similar rates of success, conversion, and complications. They reported no port-site recurrences or metastases in either the abdominal or thoracic cohorts of their study. Although a feared complication, the incidence of port-site recurrence is rare in thoracic cases (a single report by Sartorelli and colleagues).[42] However, abdominal port-site recurrence rates are higher but depend on the tumor involved.[43-46] Needless to say, these are retrospective data spanning many institutions, surgeons, tumors, and techniques. The conclusions reached by Spurbeck and colleagues attest to the safety and efficacy of MIS techniques in the successful diagnosis of pediatric tumors, but its use in the formal extirpation of tumors remains to be established.

A recent analysis by de Lijster and colleagues[47] attempted to define the role for and success of MIS techniques versus open procedures in pediatric abdominal and thoracic tumors, but they discovered that there were no randomized controlled or controlled clinical trials on this topic in the literature. Hence no formal recommendation could be made as to the effectiveness, superiority or equivalency of MIS techniques versus open procedures in childhood tumors. Obviously this topic deserves greater scrutiny and investigation through the development and completion of a rigorous controlled trial as has been done in adults.

Extremity Tumors

Biopsy of a soft-tissue or bone tumor in an extremity should be considered the first interventional procedure in limb salvage. Although the technical aspects are quite simple, the decision-making process is not. At risk are not only the patient's limb, but also overall disease control and outcome.

As noted, biopsy is truly a multidisciplinary process involving medical oncologists, surgeons, radiologists, pathologists, and radiation oncologists. Accuracy and outcome of biopsy procedures are improved when each of these specialists has a knowledge of musculoskeletal tumors and limb salvage principles. This is often best accomplished at tertiary centers with experience in the management of sarcomas.[48,49]

The first step in planning a biopsy is performing a complete work-up. Based on history and physical examination findings, suspicion is raised about a tumor. Plain radiographs are often diagnostic of a bone malignancy and are crucial. MRI is also essential for both bone and soft-tissue tumors to define the extent of the tumor itself and involvement of neighboring compartments and neurovascular structures. It should be performed before biopsy to avoid artifact signal. Ultrasound is helpful to determine whether a soft-tissue mass is cystic or solid, but MRI is the gold standard for the evaluation of a suspicious mass.

Based on the findings from the work-up, a differential diagnosis can be established through collaboration at a multidisciplinary conference. All the specialists involved should be aware of the potential of a malignancy so that proper techniques are used for the procedure itself and for handling of the tissue. The biopsy approach is selected by the surgeon based on knowledge of limb-salvage surgery. The biopsy tract should be along the planned incision for limb salvage so that the entire tract can be excised later with the resection of the tumor. This is critical, because errors in placement of the biopsy incision can contaminate neurovascular and other important structures, making limb salvage impossible or necessitating large soft-tissue flaps for coverage.[48,49] The tumor should be approached in the most direct manner and through a muscle, not in between muscles, to decrease contamination of normal tissue.

Biopsy of an extremity tumor can be performed by open or closed (CNB) techniques (Table 49-1). Open biopsy offers the advantage of a larger tissue sample so that adequate pathologic evaluation can be performed. However, the major disadvantages are a higher risk of contamination of critical structures and complications such as bleeding, infection, and pathologic fracture. It is also more expensive and requires more time. Incisional

TABLE 49-1 Comparison of Open versus Needle Biopsy

	Open	Needle
Sample size	Larger	Smaller
Accuracy	Higher or equivalent	Lower or equivalent
Morbidity	Higher	Lower
Risk of contamination	Higher	Lower
Complications	Higher	Lower

biopsy is performed by entering into the tumor itself and removing a small section of it. The pseudocapsule is repaired, and careful hemostasis is obtained to try to decrease tumor-cell spillage or creation of a hematoma. Excisional biopsy involves removing the whole tumor in one piece. This is rarely indicated for extremity tumors, because resection surgery for malignant tumors is so vastly different from that for benign tumors. Also, most musculoskeletal tumors are treated with neoadjuvant therapy before excision. This approach is used for two reasons. First, it will increase the ability to perform limb-salvage surgery. Second, it provides an in vivo assay of response to standard chemotherapy (see Neoadjuvant Therapy for Solid Tumors).

Needle biopsy on the other hand is associated with less morbidity for the patient. It carries a lower risk of complications and contamination and is often simpler to perform. However, the smaller tissue sample size is a disadvantage and decreases the accuracy rate of the diagnosis. Use of a large-bore needle to remove a core of the tumor is thus usually more advantageous than FNA, as discussed. Sampling error is another disadvantage of CNB. Image-guidance with CT (Fig. 49-12) or ultrasound improves accuracy and decreases sampling error, but it is imperative that the surgeon discuss the approach with the radiologist performing the procedure. There is a risk of local recurrence if the needle biopsy tract is not excised with the tumor, but the risk is probably less than with open biopsy.

Pathologic analysis also requires specific knowledge of musculoskeletal tumors, especially with smaller sample sizes. The specialist obtaining the biopsy should discuss the case with the pathologist. A frozen section at the time of biopsy is essential, not for definitive diagnosis, but to ensure sufficient neoplastic tissue is available to the pathologist to make a diagnosis. Proper tissue handling is also crucial for the pathologist to be able to arrive at the correct diagnosis. Hematoxylin and eosin staining as well as most immunohistochemistry can be performed on tissue placed in standard formaldehyde. However, electron microscopy, cytogenetic investigation, tissue culture, flow cytometry, and immunofluorescence all require special handling and often fresh tissue. The discovery of specific cytogenetic abnormalities in certain tumors (e.g.,, t[11;22] in Ewing sarcoma [EWS] and t[2;13] in alveolar rhabdomyosarcoma) has increased the ability of pathologists to make the diagnosis with small tissue samples, but they must be processed in the correct manner.

Combined discussion of the pathology completes the biopsy process. The multidisciplinary team caring for the patient can then review all of the staging studies with the known diagnosis in mind and arrive at a recommendation for treatment.

NEOADJUVANT THERAPY FOR SOLID TUMORS

Wilms Tumor

Cooperative group trials by the NWTSG in North America, the International Society of Paediatric Oncology (SIOP) in Europe, and the United Kingdom Children's Cancer Group (UKCCG) have provided a great wealth of information regarding the optimal management of Wilms tumor. A major difference in approach exists between SIOP and NWTSG. In North America, primary resection followed by chemotherapy and radiotherapy is favored. In the SIOP studies, children generally first receive either chemotherapy or radiotherapy followed by resection. This approach has been driven by a high incidence of operative tumor rupture in their early series. In SIOP 1 the use of preoperative radiation therapy (20 Gy) was randomized versus primary resection. The rate of intraoperative rupture decreased from 33% to 4% with the use of radiation.[50] Survival was not affected, and the incidence of local recurrence was not reported. The frequency of operative rupture that occurred in NWTS 1 and 2 were 22% and 12%, respectively.[51,52] In a subsequent SIOP study, preoperative therapy was randomized between abdominal radiation (20 Gy) and actinomycin D compared with those receiving vincristine and

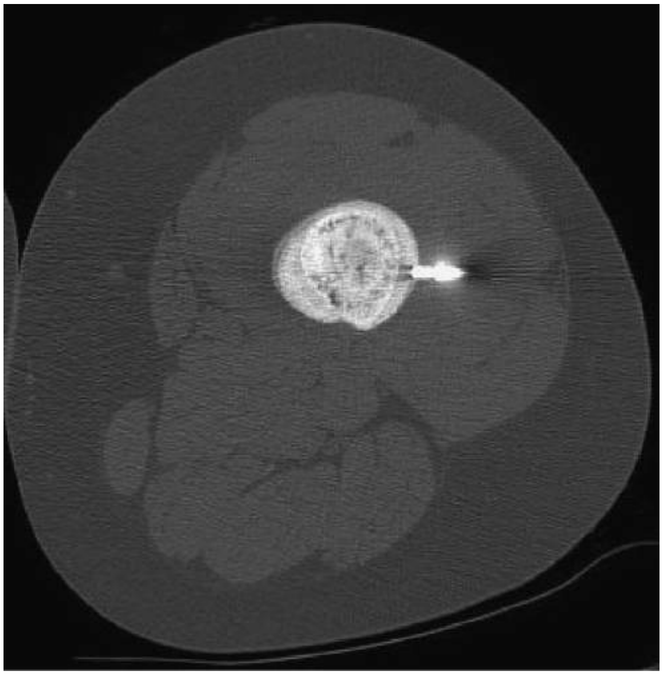

Figure 49-12 Core needle biopsy of an osteosarcoma of the femur under guidance with computed tomography.

actinomycin D. The frequency of rupture was 9% and 6%, respectively.[53]

In SIOP 6, which started in 1980, all patients received initial preoperative chemotherapy (vincristine and actinomycin D). Radiotherapy was given after resection to children with stage II N1 and stage III disease. Children with stage II N0 disease were randomized to receive either 20 Gy abdominal radiotherapy or no radiation. All children received vincristine and actinomycin D for 38 weeks. The radiotherapy randomization was halted after 123 children were randomized, 64 to radiotherapy and 59 to chemotherapy alone. Six of the 59 children who did not receive radiotherapy had local recurrences, whereas no recurrences occurred in the group who did. These findings suggest that prenephrectomy treatment altered the pathologic findings that would have led to a diagnosis of stage II N1 or stage III disease (i.e., lymph-node involvement or capsular penetration), resulting in the standard administration of local radiation. No statistical difference in survival has been seen in these children after extended follow-up observation, because those who relapsed had treatment alternatives.[54,55]

In SIOP 9, which began in 1987, preoperative therapy was randomized between 4 and 8 weeks' duration. The goal was to produce a larger proportion of stage I tumors.[56] In this study, postoperative radiotherapy for children whose disease was stage II N0 was replaced with an anthracycline (epirubicin or doxorubicin). Preoperative treatment for patients without distant metastases consisted of four weekly courses of vincristine and three 2-day courses of actinomycin D every 2 weeks versus 8 weeks of the identical therapy. There was no advantage seen from the extended therapy in terms of staging at resection (stage I, 64% versus 62%) or in intraoperative tumor rupture (1% versus 3%). Therapy after resection was based on the pathologic findings. In SIOP 9, the surgery-related complications were reported to be 8%.[57]

In both the NWTSG protocols and those of the COG, primary surgical resection is generally recommended. There are certain generally accepted situations where preoperative therapy is appropriate. These include the occurrence of Wilms tumor in a solitary kidney, bilateral renal tumors, and respiratory distress from extensive metastatic disease in the lungs. In these cases pretreatment biopsy should be obtained, and percutaneous biopsies are often used. Although needle tract seeding has been reported, this is quite rare in Wilms tumor. The aim of neoadjuvant treatment in the bilateral tumors and solitary kidney is to preserve the maximum amount of renal parenchyma and function. Current COG protocols for bilateral renal tumors have intensified the neoadjuvant therapy to include three agents (vincristine, actinomycin D, and doxorubicin) with each cycle of therapy. The duration of therapy has also been limited to avoid incremental increases in the intensity of therapy when further regression in the size of the tumor is unlikely.

The efficacy of preoperative treatment to achieve partial nephrectomy in patients with unilateral Wilms tumors has been evaluated by several centers. McLorie and associates in Toronto obtained percutaneous biopsy in 31 children with Wilms tumors. Multiagent chemotherapy was then administered for 4 to 6 weeks. Partial nephrectomy was performed in nine children (four with unilateral tumors and five with bilateral tumors).[58] Two of these children suffered an intraabdominal relapse, and only four of the 30 unilateral tumors (13.3%) were amenable to partial nephrectomy. Hence in unilateral cases not identified by prospective radiographic imaging in patients with syndromes, a partial nephrectomy is rarely possible even with preoperative therapy. Another assessment of the feasibility of partial nephrectomies was performed at St. Jude Children's Research Hospital.[59] The preoperative CT scans of 43 children with nonmetastatic unilateral Wilms tumor were reviewed. The criteria used to define those tumors suitable for partial nephrectomy were involvement by the tumor of one pole and less than one third of the kidney, a functioning kidney, no involvement of the collecting system or renal vein, and clear margins between the tumor and surrounding structures. Only two of 43 scans (4.7%) met the criteria, suggesting that a partial nephrectomy was feasible. The primary concerns regarding the administration of preoperative chemotherapy (as in the studies of Kozzi and associates and Moorman-Voestermans and co-workers) to create "resectable" small tumors is that these children may be curable by surgical resection alone without subjecting them to the toxicity of additional treatments.[60,61]

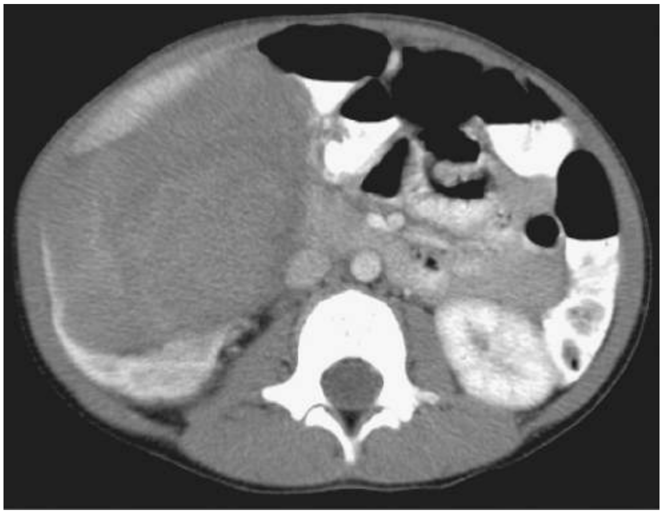

Figure 49-13 Computed tomography scan in a 4-year, 10-month-old girl who had a palpable abdominal mass. The study revealed a large tumor with a very thin renal capsule. A primary resection was performed, and the tumor was stage II with favorable histology. She went on to receive double agent therapy with vincristine and actinomycin D.

The surgical resectability of Wilms tumors has been poorly correlated with radiographic studies. In fact, extremely large tumors can be stage II lesions and be fairly safely resected (Fig. 49-13). The surgical recommendations in the NWTSG studies have been that if resection of the tumor would involve resection of adjacent organs (i.e., liver, pancreas, or spleen) because of adherence, biopsies should be obtained and subsequent chemotherapy applied before resection, because such resections are associated with an increased rate of complication (Fig. 49-14). Complications in the NWTSG-4

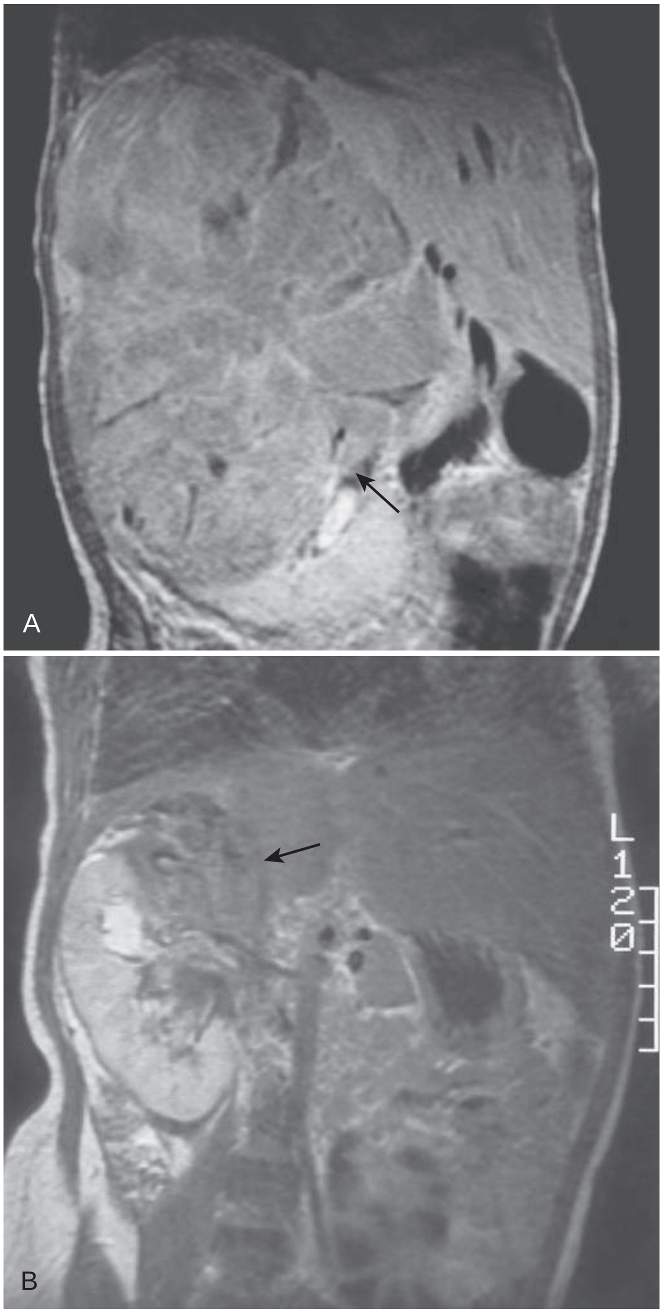

Figure 49-14 **A**, Magnetic resonance imaging (MRI) scan of a 2 and a half-year-old girl first seen with a massive right-sided abdominal mass *(arrow)* that appeared to arise from the kidney. Chest radiograph revealed pulmonary nodules as well as stage-IV disease. Because of the size of the primary tumor and the presence of metastatic disease, she received neoadjuvant chemotherapy after needle biopsy demonstrated a standard-risk tumor (diffuse blastemal subtype). She first received three courses of actinomycin D, vincristine, and cyclophosphamide, which achieved some shrinkage of the tumor. At attempted resection, the extensive tumor was densely adherent to the posterior aspect of the liver and the vena cava. The attempted resection was halted at that time, because it was clear that a portion of the liver would have to be resected with the nephrectomy. Repeat biopsies again demonstrated a standard histology Wilms tumor with tumor invasion into the liver. She then received more intensive therapy involving cisplatin and VP-16, as well as abdominal and thoracic radiation. **B**, MRI after additional therapy showed remarkable shrinkage of the tumor, allowing a less extensive and safer resection. A plane could be developed between the liver and kidney at this point, and hepatectomy was not required.

study have been assessed.[62] Complications occurred in 12.7% of a random sample of 534 of the 3335 patients enrolled on the study. Intestinal obstruction was the most common complication (5.1%), followed by extensive hemorrhage (1.9%), wound infection (1.9%), and vascular injury (1.5%). Factors associated with an increased incidence of complication included intravascular extension into the inferior vena cava or atrium and nephrectomy performed through a flank or paramedian incision. Tumor diameter greater than or equal to 10 cm was also associated with increased complications. In SIOP 9, complications occurred in 8% of 598 patients. These patients were pretreated with vincristine, actinomycin D, and epirubicin or doxorubicin before nephrectomy.[57] Their complications included small bowel obstruction in 3.7% and tumor rupture in 2.8%. The latter is not reported as a complication in the NWTSG reviews.

Neuroblastoma

Surgery plays a primary role in the treatment of low-stage neuroblastoma. Tumors that the surgeon deems readily resectable should generally have a primary resection for staging and to establish both the diagnosis and the biologic risk factors of the tumor. In many children with small tumors and favorable biologic factors, surgery is the only therapy required. Resection is generally accepted before administration of chemotherapy for most thoracic, pelvic, and cervical primaries and limited abdominal lesions that do not extend across the midline. This approach is used to avoid the toxicity of chemotherapy, and in many patients with low-stage favorable biology tumors, resection alone is curative. In those situations where resection would entail removal of vital organs or where there is extensive lymph-node extension, preliminary treatment with adjuvant chemotherapy, particularly in the biologically adverse tumors, would be most appropriate. In patients with favorable biologic features, even subtotal resection may be the only therapy required.[63]

Of note, however, is the report by Nuchtern and colleagues[64] documenting the results of the COG trial on expectant management in infants (younger than age 6 months) with small adrenal masses. Eighty-seven cases were enrolled, and four patients were elected for upfront surgery. Of the remaining cohort, only 16 other patients had their adrenal lesions resected, with neuroblastoma diagnosed in 10 children, low-grade adrenocortical tumors in two, adrenal hemorrhage in two, and extrapulmonary pulmonary sequestrations in two. The overall, 3-year survival rate in the entire cohort was 100%, with a neuroblastoma event-free survival (EFS) of almost 98%. These results are quite encouraging in defining a cohort of children who can be spared any treatment for small adrenal-based neuroblastomas, but the suitable application of these data to nonadrenal primary sites, larger tumors, and in older children remains to be determined.

Regrettably, the majority of infants and children have metastatic disease at diagnosis. In these cases, the diagnosis and biologic features must be established. Tissue may be obtained by either laparotomy or thoracotomy, as well as by laparoscopy and thoracoscopy. In older patients with metastatic disease where Shimada staging is not required to determine the patient's treatment, needle biopsy from either bone marrow or the primary metastatic tumor provides adequate material for both pathology and biologic grading. For patients in whom the Shimada criteria are critical to determine their therapeutic treatment, open or minimal access surgery is required to obtain adequate tissue.

In patients with extensive abdominal primary tumors, adjuvant therapy has been useful. It is well recognized by surgeons that preoperative chemotherapy decreases the vascularity and friability of the tumor and facilitates resection, particularly in developing the dissection plane between the tumor and the great vessels.[65] Lymph-node involvement surrounding the aorta, vena cava, and renal vessels is often seen in children with advanced stage abdominal adrenal or paravertebral primaries (Fig. 49-15).

Although two studies have shown no difference in the surgical complication rate between initial and postinduction resection, others have demonstrated a higher incidence of complications, including nephrectomy in the group undergoing primary resection.[66,67,68-71] Furthermore in patients with high-risk tumors who often require autologous bone-marrow transplant, preservation of the ipsilateral kidney during the resection is critical.[72] A neoadjuvant approach has contributed to decreased operative complications requiring nephrectomy.[73]

A multiinstitutional review of children treated over an 11-year interval demonstrated a 14.9% incidence of nephrectomy or renal infarction as a result of surgery for local control (52 of 349 children). There was a 25% incidence among those with initial resection (29 children) and a 9.9% incidence in the postchemotherapy resection (23 children). Children with initial resection had more than a twofold increase in their risk of nephrectomy. Hence the approach for neuroblastoma regarding primary lesions is quite different from that in Wilms tumor. The other determining factor is that the pathologic staging information is not as critical for determining local control in neuroblastoma as in Wilms tumor, and essentially all of these children with large primary lesions require adjuvant chemotherapy and radiation. Hence administration preoperatively in no way increases the chance that chemotherapy will be required and is generally recommended in most current protocols.

Of note, however, is the report from Simon and colleagues[74] reporting the results of the German cooperative trial NB97 that evaluated the role of surgery (upfront and postneoadjuvant therapy) in patients older than 18 months with stage IV disease. In this study, 278 patients were evaluated, and their data report that neither upfront surgery nor operations performed postneoadjuvant chemotherapy positively impacted EFS, local progression-free survival (LPFS), or overall survival (OS). They concluded their manuscript by calling into question the role and utility of surgery in this patient cohort secondary to the lack of compelling data supporting effective local control or survival rates. Obviously, more data are required to definitively answer these questions.

Hepatoblastoma

Surgery is the cornerstone in the treatment of hepatoblastoma, and children are rarely cured without resection. Neoadjuvant and adjuvant chemotherapy facilitates its feasibility and success. Historically, resection with complete removal of all radiographically identifiable disease cured only 25% of children; 50% of children who presented with hepatoblastoma had resectable lesions, and of those only 50% survived.[75,76] Failure was attributed to occult metastatic disease not identified radiographically,[77] and Weinblatt and colleagues[78] reported the early success of neoadjuvant chemotherapy to convert unresectable liver tumors to resectable lesions with more than 75% of the lesions becoming resectable in both series (Fig. 49-16).

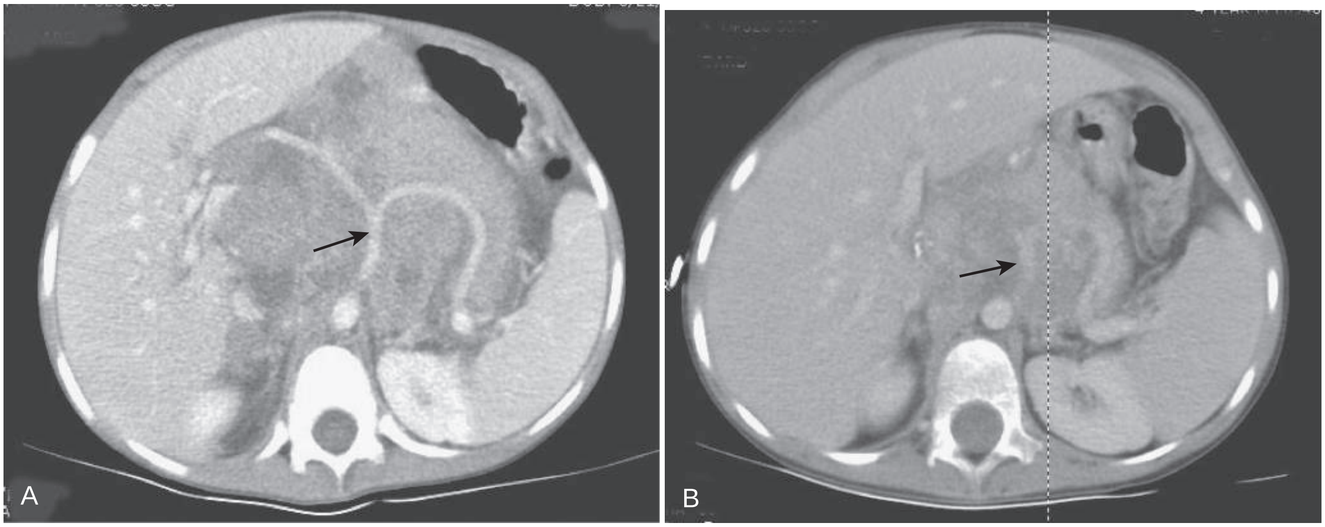

Figure 49-15 Four-year-old with bone pain and palpable abdominal mass. Computed tomography (CT) showed an extensive mass arising from the adrenal gland (**A**). This scan shows extensive involvement of the lymph nodes around the aorta with the celiac axis projecting anteriorly surrounded by tumor. In this section, the splenic artery as well as the hepatic artery are demonstrated surrounded by tumor. Subsequent CT (**B**) after four courses of multiagent chemotherapy revealed marked resolution in the size of the mass, although it still surrounded the celiac axis *(arrow)*.

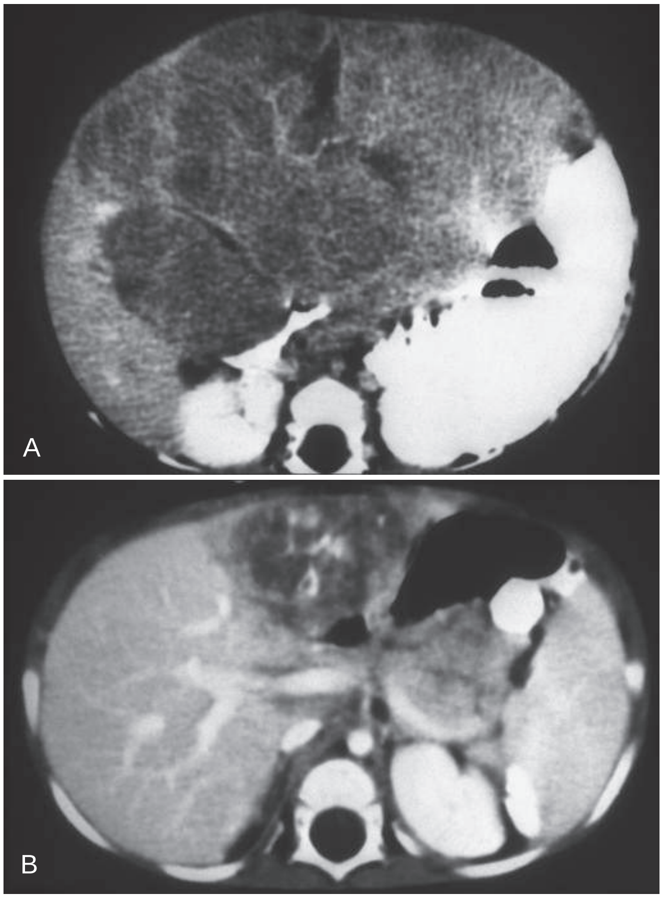

Figure 49-16 A 9-month old female with a palpable abdominal mass extending to below her umbilicus. **A**, Computed tomography (CT) scan revealed an extensive mass in her liver. **B**, CT scan after four courses of chemotherapy showed remarkable resolution of the mass that was subsequently resected by a left trisegmentectomy.

Only children with tumors with pure fetal histology do not require adjuvant therapy.[79] Subsequent reports document the utility of various chemotherapeutic regimens in hepatoblastoma to treat unresectable lesions or residual disease.[80-83,84-86] These reports establish the efficacy of doxorubicin, cisplatin, vincristine, and 5-fluorouracil alone or in various combinations. Cisplatin has been shown to be as efficacious as cisplatin with doxorubicin for standard-risk hepatoblastoma.[87] Furthermore both adjuvant and neoadjuvant regimens in combination with surgery achieved survival rates greater than 65% and tumor response rates greater than 90%. Although the regimens varied, most patients received at least two cycles before definitive surgery. The extent of tumor necrosis has also been shown to predict survival, as does negative surgical margins.[88] The critical need for resection of the primary tumor before the development of chemoresistance was demonstrated by von Schweinitz and colleagues.[84] They documented tumor regrowth as early as after the fourth course of therapy in 6 of 11 patients. Five-year survival rates for all patients with hepatoblastoma increased in just 2 decades to over 85% with the use of neoadjuvant and adjuvant chemotherapy.

Since 2000, a defined treatment protocol consisting of neoadjuvant chemotherapy and surgical resection or early orthotopic transplant evaluation for those patients with tumors that are too extensive to resect has been developed and reported by the SIOP Liver Tumor Group (SIOPEL).[89,90] This regimen was termed *PLADO,* and it consisted of a pretreatment imaging-defined staging protocol (PRETEXT), pretreatment diagnostic biopsy (core needle or incisional biopsy), neoadjuvant chemotherapy of continuous infusion cisplatin (day 1) followed by continuous infusion of doxorubicin (days 2 and 3), surgical resection after 4 to 6 cycles 12 to 20 weeks from diagnosis, and orthotopic liver transplant (OLTX) evaluation and referral for tumors confined to the liver that remained unresectable despite chemotherapy. The only tumors resected primarily were those deemed to be confined to a single section of the liver (i.e., right anterior, right posterior, left medial, left lateral; PRETEXT stage I). The overall 5-year survival rate was 75% for the entire cohort and 85% for those following the complete protocol, including neoadjuvant chemotherapy regardless of PRETEXT stage. PRETEXT stages I through IV had OS rates of 100%, 91%, 58%, and 57%, respectively, which compares favorably with survival rates achieved by Ortega and colleagues[91] through a CCG/POG cooperative trial comparing multimodality treatment protocols utilizing different chemotherapeutic regimens. Surgical mortality was 6%, and overall mortality was 24%. Twenty percent of patients had pulmonary metastases. Ninety-two percent of patients had a complete resection with this protocol, and there were 10 patients who relapsed: five with local recurrences and five with pulmonary metastases. SIOPEL's use of OLTX as primary treatment for local control was published by Otte and colleagues.[92] Those patients whose tumors involved all sectors of the liver or were intimately involved with either the hepatic or portal veins but had no evidence of metastatic disease and demonstrated some response to neoadjuvant chemotherapy were considered for a primary OLTX. Another cohort of patients who had intrahepatic recurrences of disease after resection or incomplete resections was eligible for rescue OLTX. Ten-year survival rates for the primary and rescue OLTX groups were 85% and 40%, respectively. The authors advocated, based on their results, for the following: 1) total resection of all gross disease including the retrohepatic vena cavae if needed; 2) the use of preoperative chemotherapy to control extrahepatic micrometastases and promote primary tumor regression; 3) transplantation for patients with synchronous pulmonary metastases if they had responded to neoadjuvant therapy; 4) no transplantation for those patients with evidence of metastatic disease present at surgery; 5) limiting the interval between diagnosis and OLTX to account for the rise of chemoresistance and the availability of donors (cadaveric or living); and 5) questioning the need of post-OLTX chemotherapy in the setting of a patient with immunosuppression. Although their cohort was small (12), they reviewed the world's experience with OLTX for hepatoblastoma in the same report, and the results were similar. As a corollary to this report, Austin and colleagues[93] reported on the experience of the United Network of Organ Sharing (UNOS) for 152 OLTXs performed in 135 patients in the setting of hepatoblastoma. Their actuarial 1-, 5-, and 10-year survival rates were 79%, 69%, and 66%, respectively. More than 54% of patients died of recurrent disease, and the only statistically significant predictors of favorable outcome were the preoperative condition of the patient (intensive care unit [ICU] hospitalization versus non-ICU hospitalization versus no hospitalization) and the era when the patient received the transplant (before or after December 31, 1994). These reports document not only the feasibility but also the success of OLTX as a component in the multimodality treatment of hepatoblastoma.

Rhabdomyosarcoma

Except for Wilms tumor, no other pediatric solid tumor has benefited so greatly from the combined efforts of oncologists of all disciplines in forming multimodality protocols designed to adequately diagnose, stage, and treat a lesion as has rhabdomyosarcoma. The 5-year survival rate of children with this disease was less than 25% before 1972 when the IRS study group was formed.[93,94] During the next 3 decades, this figure has increased almost threefold to 70%.[95-97] Because rhabdomyosarcoma is a tumor of mesenchymal origin, it may appear almost anywhere in the body and from almost any organ. Treatment protocols and outcomes vary greatly depending on the site and stage of the tumor. Initial pretreatment evaluations document the characteristics of the primary lesions and the regional lymph-node basins. If an extremity lesion is excised with positive margins and proves to be a rhabdomyosarcoma, it has been shown that pretreatment reexcision with generous margins (0.5 cm or greater) of uninvolved tissues and local lymph node sampling results in improved survival.[98] Debilitating resections producing loss of function are not currently warranted, except in cases with residual disease after adjuvant radiotherapy and chemotherapy. Regional and distant lymphadenopathy diagnosed clinically or radiographically must be biopsied to establish the presence or absence of tumor that will impact treatment strategies and prognosis.[99] Aggressive lymphadenectomies are not warranted, but a stepwise progression of draining lymph-node basins should be sampled to determine the lymph-node status of these contiguous basins and hence the extent of regional radiotherapy. Finally, so called "second-look" operations performed on the primary site in IRS III proved useful in the excision of residual tumor, the confirmation of the effectiveness of adjuvant therapies, and the improved prognosis of all tumors except for pelvic sites that had a pathologically confirmed complete response to therapy.[100] These principles of complete resection of the primary tumor and lymph-node biopsy determine postoperative clinical groupings that determine adjuvant treatment therapies and prognosis.

Radiotherapy is a core modality of treatment for local control, and its field is based on the size of the mass before resection. Patients receive a radiation field with at least a 2-cm margin around the primary mass. Therapy is generally begun 8 to 12 weeks after initiation of chemotherapy and continues for 5 to 6 weeks. All histopathologic subtypes except group I embryonal disease receive radiation therapy.[97] All other groups and rhabdomyosarcoma variants receive at least 4000 rads for microscopic residual disease and as much as 5000 rads for macroscopic residual disease,[97,101,102] providing a strong basis for primary resection if safely feasible.

Adjuvant chemotherapy is critical, and its use is based on a risk stratification schema that incorporates tumor site of origin, tumor histopathology, tumor-nodes-metastasis (TNM) staging, and the postoperative clinical grouping. Patients are stratified into low-, intermediate- or high-risk categories. Patients with low risk typically receive a three-drug regimen of vincristine, dactinomycin, and cyclophosphamide. Patients with intermediate risk generally receive the same three-drug regimen, but those with tumors from favorable sites and those with completely resected tumors from unfavorable sites receive dose-intensified cyclophosphamide.[102] Patients at high risk, however, should receive a two-drug regimen of ifosfamide with etoposide or doxorubicin.[103,104] Patients with metastatic disease or alveolar subtypes should also receive topotecan or irinotecan in addition to standard therapy.[105,106] Ideally, neoadjuvant chemotherapy can reduce tumor burden and convert unresectable lesions to resectable ones with decreased patient morbidity (Fig. 49-17).

Osteosarcoma, Ewing Sarcoma

The single most important factor in improved survival for patients with osteosarcoma (OSA) or Ewing sarcoma (EWS) has been the development of effective chemotherapy. Before 1970, patients with OSA had an OS of around 10%. Before the 1960s, survival was even less than 10% for patients with EWS. Ablative surgery and/or radiation were the only modalities available at that time. Local control, however, was not the issue. Patients succumbed primarily from metastatic disease that was believed to be present at diagnosis, although it could not be demonstrated radiographically. Systemic treatment was necessary to achieve improved survival and cure. Medications were identified and successfully applied in cooperative multiinstitutional trials. With modern chemotherapy protocols, OS for OSA is now 60% or better and approaches 60% for EWS.

Current protocols for OSA involve neoadjuvant chemotherapy, surgery, and then further adjuvant chemotherapy. Protocols are similar for EWS except that radiation can be used in combination with surgery or alone as local treatment. The advantages of this approach are that tumor cells in the primary tumor and in micrometastatic form are treated immediately and that histologic response to the chemotherapy can be assessed. The potential advantage of making limb salvage surgery safer is debatable, but certainly, any reduction in size of the primary tumor improves the feasibility of surgical resection (Fig. 49-18). The disadvantages are that in patients who do not respond to the usual drugs, their disease may progress, and drug resistance may develop. Because response to chemotherapy has been identified as one of the more important prognostic factors with potential

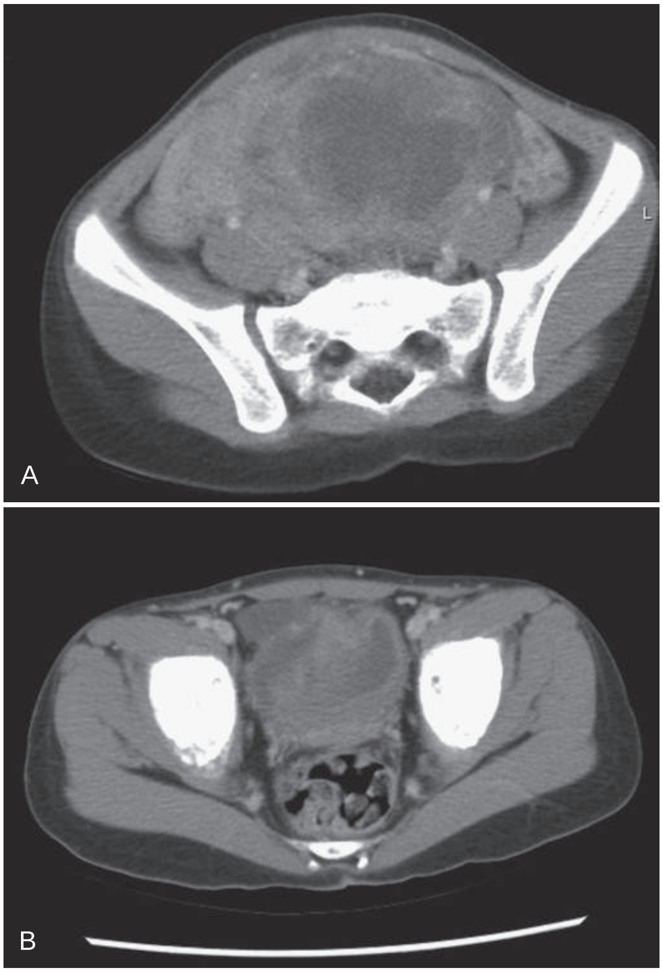

Figure 49-17 **A**, A 7-year-old with a large bladder rhabdomyosarcoma prechemotherapy. **B**, A significant decrease in the size of the tumor.

implications for changes in therapy, this overall approach is used in the majority of trials. The reality, though, is that no new drugs or changes in therapy have been shown to improve survival to any great extent in poor responders. Efforts to improve survival for poor responders and for patients who relapse are the focus of current protocols and research.

LIMB SALVAGE PROCEDURES

Surgical Principles

The surgical treatment of bone sarcomas has evolved from the prechemotherapy era where all patients had amputations, radiation therapy, or both, to the current practice where 80% of patients or more receive a limb-salvage resection.[107] The resection can be thought of in two phases: wide resection of the tumor and involved bone and the reconstruction, for which there are multiple alternatives. A “safe” resection requires complete excision of the involved bone and soft tissues with a cuff of normal tissue surrounding the entire specimen, a so-called *wide margin*. The necessary thickness of this cuff of tissue and the length of normal marrow away from the tumor is not precisely known,[108-112] but at a minimum there should not be “ink on tumor.” While experience with these operations grows, most surgeons now accept soft-tissue margins of 2 to 5 mm of normal soft tissue and 1 to 2 cm of marrow margin, but there is no evidence-based minimum margin that has been documented to be safe with respect to local recurrence. Neoadjuvant chemotherapy probably lessens the likelihood of a local recurrence.[113-116] Recent data would suggest that a wide margin in a patient with a good response to chemotherapy has a low likelihood of local recurrence.[117,118,119] Resections with a narrower margin (marginal or intralesional) and/or those with a poor response to chemotherapy have a higher risk of local recurrence. It is clear that a local recurrence is associated with a poor prognosis for survival.[120-123]

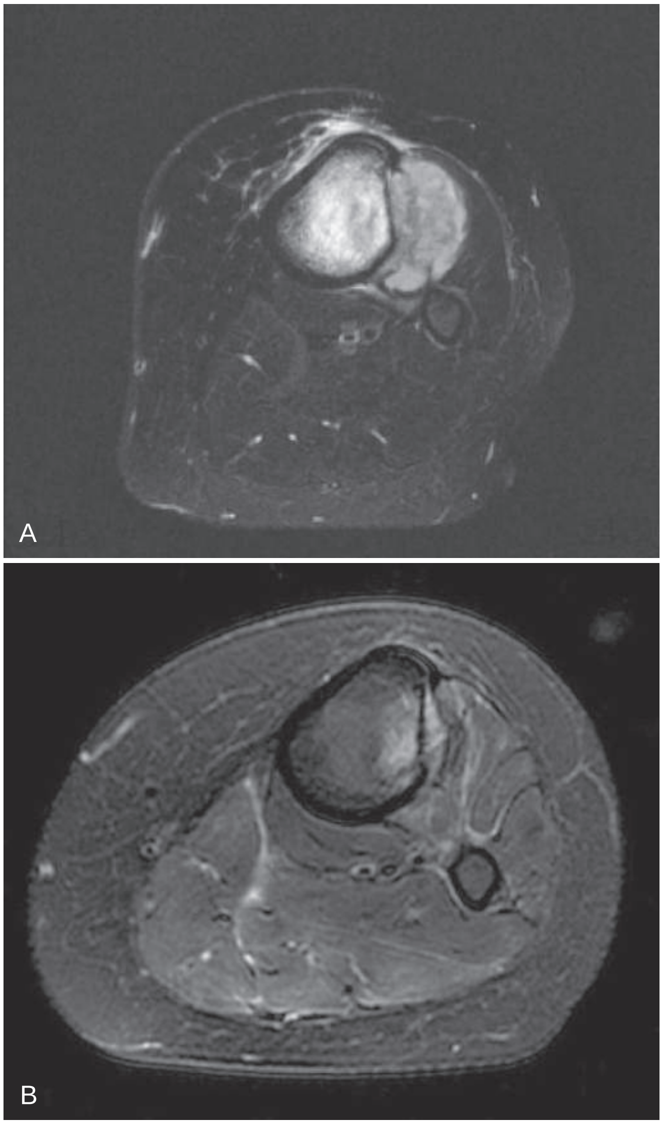

Figure 49-18 Ewing sarcoma of the proximal tibia: T2-weighted sequence with fat saturation, axial magnetic resonance imaging. **A**, At initial diagnosis; note the large anterolateral soft-tissue extension outside of the bone. **B**, After neoadjuvant chemotherapy, the soft-tissue mass has noticeably decreased in size, making surgery, especially dissection around the arterial trifurcation, less difficult.

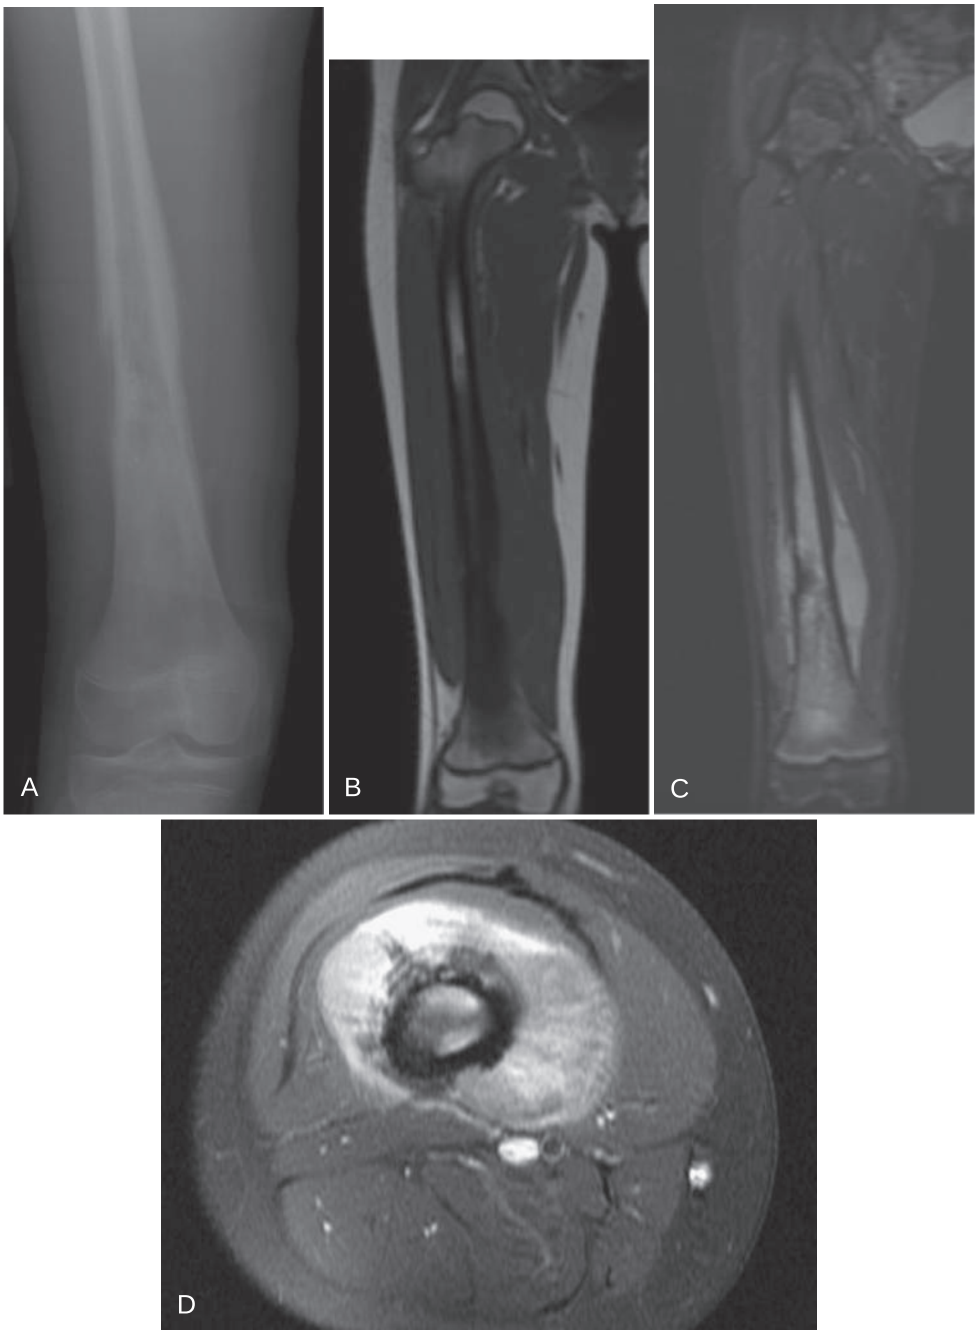

Figure 49-19 **A**, Osteosarcoma of the femur showing ill-defined bone destruction in the metaphysis and soft tissue mass. **B**, Coronal T1-weighted images show the extent of the tumor in the medullary canal. **C** and **D**, Coronal and axial images show the extent of the soft-tissue mass and the relationship to the femoral artery and vein.

The decision of resection versus amputation and the type of reconstruction requires careful evaluation of the imaging studies with a multidisciplinary team that includes an experienced musculoskeletal radiologist and a detailed discussion with the patient and family regarding the alternatives. Although most patients would prefer to save their limb if possible, it should be understood that current reconstruction options cannot restore a normal limb and most are not meant to return the patient to athletic activities. Patients with lower-extremity primary tumors who want to continue contact and running sports are better served with an amputation or rotationplasty.

The resection requires a careful analysis of the radiograph and MRI. The entire bone should be imaged to exclude the possibility of skip metastases. MRI is the best study to assess the extent of the tumor within the bone and soft tissue (Fig. 49-19).[124-128] OSAs may cross growth plates to involve the epiphysis of the bone, but they rarely cross the articular cartilage unless there has been a fracture.[124,126] Adjacent joint involvement is rare, but if present it requires an extraarticular resection. Tumors may enter the joint by extending along the joint capsule (e.g., in the proximal humerus the metaphysis is partially intraarticular) or cruciate ligaments (knee) or ligamentum teres (hip). The major nerves and vessels must be uninvolved or resectable to achieve the required margin. Finally, there must be sufficient muscle remaining after the resection to allow soft-tissue coverage of the reconstruction and to power the limb. At times rotational flaps or free-tissue transfers may be indicated to obtain soft-tissue coverage and lessen the chance of a wound complication.[129,130] For all resection types, infection is the worst immediate complication and its incidence can be lessened with adequate soft-tissue closure.

Once the resection has been completed, the pathologist should examine the specimen grossly to ensure complete resection. The use of frozen section analysis of the marrow margins is a routine and accepted practice but is of uncertain value.[131] Bisecting the specimen with a band saw and visualizing it will reassure the surgeon that an adequate resection has been accomplished.

Types of Reconstruction in Children

Reconstruction options include the use of metallic endoprostheses, bone allografts, and rotationplasty. Some sites require no bony reconstruction. These "expendable" bones include the fibula, clavicle, rib, and iliac wing (if the acetabulum can be preserved). Most OSAs are located about the knee, hip, and shoulder and involve resection of the distal femoral, proximal tibial, proximal femoral, or proximal humeral metaphysis and epiphysis. In addition to the bony defect, a major growth center is included that in the lower extremity adds complexity to the reconstruction not encountered in adults. For patients close to skeletal maturity (10 to 12 years old in girls and 14 to 16 years in boys) this is seldom a major issue and can be addressed by reconstructing with a slightly longer implant than the length resected. Limb-length discrepancies of 2 cm or less are seldom a clinical problem and can be treated with a simple shoe lift. For tumors around the knee in younger patients, limb length must be addressed by the reconstruction chosen. The alternatives include the use of an expandable prosthesis, bone allografts, and rotationplasty. Each has advantages and disadvantages. An expandable prosthesis in theory allows "growth" of the prosthesis over time but will need to be revised to an adult prosthesis at skeletal maturity.[132-136] Some of these prostheses require several operations to achieve lengthening,[136] whereas others have nonoperative mechanisms of expansion.[132] They are expensive, complex prostheses with many potential complications. Children younger than 8 years of age have difficulty cooperating with physical therapy, so joint contractures are a problem. In addition, mechanical failure of the prosthesis, metal debris, loosening, and infection can be significant problems.[137] Bone allografts have the advantage of preserving the adjacent bone and its growth plate (i.e., the proximal tibia can be preserved after distal femoral resection) but obviously have no capacity to grow. There are also issues of finding an allograft of appropriate size and shape, but if a suitable bone is available, length equalization can be addressed by inserting a graft 1 to 2 cm longer than the length resected and addressing limb length subsequently with standard pediatric orthopaedic techniques of contralateral epiphyseodesis. At skeletal maturity, closed femoral shortening and limb-lengthening techniques are also available. Rotationplasty addresses this issue because the prosthesis can be adjusted to the desired length while the child grows.

Bone Allografts

Bone allografts are used to reconstruct defects primarily at the distal femur, proximal tibia, proximal femur, and proximal humerus.[138-142] The obvious concern is transmission of bacterial and viral disease, but bone banks are now accredited by the American Association of Tissue Banks, and the safety record of these grafts is quite good since better testing for human immunodeficiency virus (HIV) and hepatitis became available.[143-145] The advantages in young patients are that they are intended to restore bone stock and joint structures (articular cartilage, ligaments, and joint capsule) and delay the need for metallic prostheses. In theory they restore bone stock, but experience has shown that the grafts are only partially replaced by host bone, and it is likely that most patients who receive osteoarticular grafts will require a joint arthroplasty at some point (5 to 20 years from the index procedure). Delaying artificial joints until adulthood is probably advantageous for long-term salvage of the limb; however, these secondary operations are challenging as well.[146] In a young child a major advantage of osteoarticular allografts is the avoidance of resection or placing an implant across the adjacent growth plate. These are complex operations, and they require the availability of a tissue bank and surgical expertise with the use of allografts. The procedure is associated with a significant complication rate. Infection, reported in the 0% to 20% range,[138-142] is the worst complication and usually requires removal of the graft. Nonunion of the allograft–host junction (reported to occur overall in 17%) is higher (27%) in patients receiving chemotherapy[147] but can usually be addressed by revision of the fixation and bone grafting of the osteosynthesis site. Fracture is a later complication and occurs in about 15% of patients.[138,140-142,147-149] Occasionally the fracture heals with conservative means, but more often revision to another allograft, augmentation with a vascularized fibular graft,[150] or conversion to an endoprostheses is required.[151] Postoperative management includes closed suction drains for 24 to 48 hours, preoperative and postoperative antibiotic coverage (there are no data regarding the necessary length of antibiotic coverage), venous thrombosis prophylaxis, and initial immobilization. Physical therapy to start joint motion is begun after 6 weeks, and the limbs are protected with crutches and bracing until the osteosynthesis site heals (approximately 6 to 9 months in patients getting chemotherapy).

Endoprostheses

Metallic prostheses were initially custom made to fit the expected bone resection defect. There are a number of available modular systems that allow the surgeon to

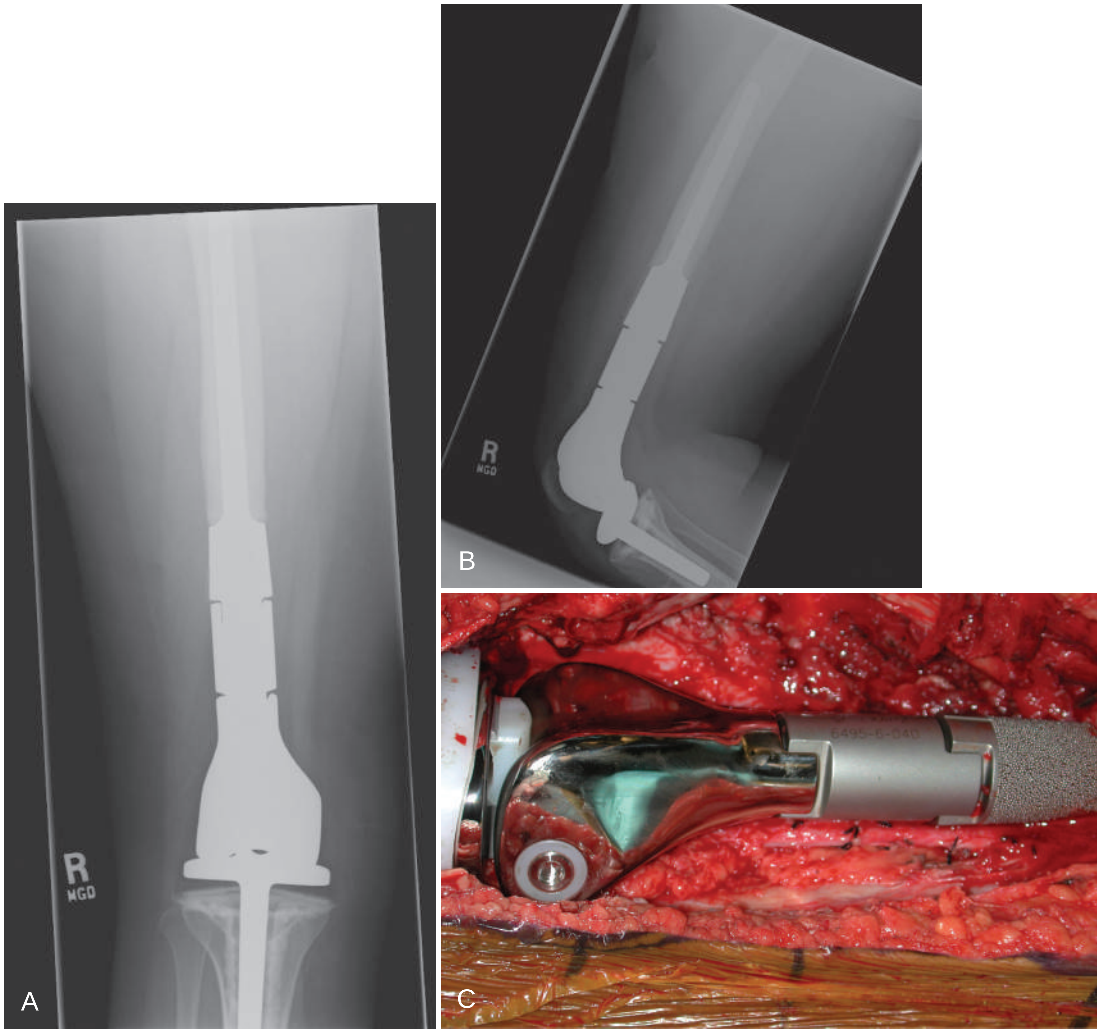

Figure 49-20 **A** and **B**, Anteroposterior and lateral views of a modular tumor prosthesis used to reconstruct after a resection for distal femoral osteosarcoma. A rotating hinge design is used, and the modular nature of the prosthesis can be appreciated. **C**, The prosthesis after insertion during the operation.

reconstruct the defect at the operating table.[152-159] In older children close to skeletal maturity, adult prostheses can be used. Most reconstructions around the knee use a rotating hinge construct that reduces the forces that are transmitted to the host-prosthesis interface, and this design is believed to increase the longevity of the implants because of delayed loosening of the stems. Modern stem designs include the option of cemented or uncemented stems, and in the femur there are curved and straight stem designs. In theory, uncemented stems offer the advantage of avoiding osteolysis and loosening, but whether bony ingrowth is reduced in patients receiving adjuvant therapies is uncertain at this time.[154,155,160,161] The main advantage to endoprostheses is that they are as stable and functional as they will ever be as soon as the wound heals, so return to function is more rapid than with allografts. Patients do not need to wait for an osteosynthesis to heal, and early weight bearing and range-of-motion exercises are permitted. The disadvantages include infection (although the reported rates are lower than with allografts), loosening or mechanical failure of the implants, metal debris, and decreased longevity.[159,160,162-165] Because 70% to 80% of children with bone sarcomas now survive, it is unlikely that these implants will last the lifetime of the patient. Revision is possible, but multiple revisions over time may limit the options and lead to amputation. The longevity (not function) of the implants is about 60% to 80% at 5 years and 50% to 80% at 10 years for lower extremity implants depending on the specific series.* The expandable endoprostheses are more complex and likely to have a higher complication rate.[132-137,170-172]

Examples by Anatomic Site

Distal Femur and Proximal Tibia

Tumors around the knee can be reconstructed by any of these methods. A few examples will be provided. Figure 49-20 shows examples of an endoprosthesis of the distal femur. The implant is a modular prosthesis that is cemented into the remaining femur and proximal tibia after an intraarticular resection. Initial function of these constructs is quite good, but it is expected that loosening will occur sometime in the future. It is known from adult arthroplasty and the early experience using custom and modular prostheses that the interface between the cement and the bone will fail over time in part because of particulate debris and the biologic response to it. Design improvements such as ingrowth surfaces near the stem–implant junction that allow bony- or soft-tissue ingrowth may delay or prevent loosening.[166] Uncemented stems may also offer longevity advantages. A further concern is stress shielding. The stem takes the mechanical load from the adjacent bone, and the host responds by resorbing the cortical bone over time. The concern is that in future revisions, insufficient bone stock will remain. There are newer stem devices that load the bone to avoid stress shielding and offer the hope of more longevity. The early data from these stems is encouraging.[173] Unfortunately, there are no direct comparisons between osteoarticular allografts (Fig. 49-21) and endoprostheses at this site, but the current literature would suggest that for the distal femur, an endoprostheses is superior.[169] Some surgeons believe that in the skeletally immature, it is still advantageous to use allografts at this site for the reasons stated.

---

*References 136, 155, 157-163, 166-169.

In the proximal tibia, an osteoarticular allograft offers the advantage of providing a site for attachment of the patellar tendon. This is much more difficult to achieve in an endoprostheses. As shown in Figure 49-22, an intraarticular proximal tibial resection is achieved including the host menisci (although they can be preserved depending on the extent of the tumor). The reconstruction allows repair of the cruciate ligaments, joint capsule, and patellar tendon. A gastrocnemius flap is sometimes required for soft-tissue coverage and is always required to augment soft-tissue attachment of the patellar tendon if an endoprostheses is used. Fixation is achieved with standard plates and screws used to treat fractures. Plates that span the entire length of the allograft or intramedullary fixation are desirable to lessen the fracture rate. Intramedullary rods require supplemental plate fixation to control rotation at the osteosynthesis site. Newer locking-plate designs may lessen the incidence of nonunion and fracture.[174] A variation of this construct is to combine an allograft and standard total knee prosthesis (allograft-prosthetic composite), usually a rotating hinge design for stability (Fig. 49-23). This approach allows a stable knee construct initially and a site for reattachment of the patella tendon. It has the disadvantage in a skeletally immature patient of placement of an implant across the adjacent (distal femoral) growth plate, creating a greater potential limb-length discrepancy.

A further option at the knee is an expandable prosthesis (Figs. 49-24 and 49-25). These can be used for the distal femur and proximal tibia. Many parents are now aware of these devices and are requesting them, but their long-term outcome is still uncertain. One could argue that an attempt at this is reasonable if the alternative is amputation or rotationplasty, planning to deal with complications later if the patient survives. The downside is that it restricts young children from normal activities including sports; if they pursue them, the likelihood of failure is higher.

Rotationplasty

For large tumors of the distal femur or very young patients with distal femoral sarcomas, rotationplasty is an excellent alternative to amputation.[175-177] A rotationplasty preserves the distal leg, foot, and ankle, and places it at the level of the contralateral knee (Fig. 49-26). The tibia replaces the femoral shaft, and by rotating the limb 180 degrees, the ankle and foot act like a knee, making the construct function like a below-knee amputation rather than a high-thigh amputation. A modification of this procedure can be performed for proximal tibial and proximal femoral sarcomas.[178-180] The margin achieved is wider than a standard resection, because with the exception of the sciatic nerve, no other structures need to be saved. The vessels can be dissected and coiled like the nerve at closure or resected and anastomosed after the osteosynthesis has been achieved. This procedure may be more suitable for patients with pathologic fracture because of the wider margin it achieves, but if the patient has a widely displaced fracture and a large sarcoma at diagnosis and requires spica immobilization during preoperative chemotherapy, there is a higher risk of the anastomosis failing because of venous congestion in the leg (personal observation). Rotationplasty has the advantage of avoiding phantom pain, because the sciatic nerve and its branches are preserved and growth is not an issue because the prosthesis can be adjusted as the patient grows. It usually requires a single operation with a low complication rate and allows the child to have full activities. The functional results are rewarding. The main drawback is the cosmetic appearance. Patients must be carefully selected, and it is essential that the child and parents meet a patient who has had a rotationplasty and work with an experienced therapist preoperatively so that they fully understand the operation. Many patients, parents, and surgeons refuse this option because it is distasteful, but those who accept it do extremely well functionally and emotionally. This has been documented in long-term studies.[175,181,182,183-187]

Proximal Femur

Resection of the proximal femur requires careful assessment of the hip joint (Figs. 49-27 and Fig. 49-28). If an intraarticular reconstruction can be achieved, the reconstruction options include either a metallic prosthesis or an allograft.[154,158,188,189] The likelihood that an allograft will fit perfectly into the acetabulum is low, so most allografts are used as allograft-prosthetic composites at this site. If the acetabulum requires resection, the reconstruction is much more complex. An allograft offers the theoretical advantage of a site for reattachment of the abductor muscles and lessening the abductor lurch during gait, but attaching the abductors to a metallic prosthesis or the iliotibial band has been shown to be quite successful and probably equivalent. The decision of whether to do a total hip prosthesis or a hemiarthroplasty is more difficult. Although the hemiarthroplasty is easier and

more stable than a total hip arthroplasty, recent data in children suggest that these may subluxate as the child grows and the acetabulum develops, necessitating revision to a total-joint arthroplasty.[190]

Pelvis

In general, patients with sarcomas of the pelvis have a worse prognosis than those of the extremities.[191-196] Assessment of response to chemotherapy is critical. For EWS, the alternative of irradiation for local control is available, but for OSA surgical resection is required even if this means hemipelvectomy if the goal is cure. Resections are difficult and often require the expertise of the orthopaedic oncologist, a surgical oncologist, and at times a vascular surgeon or urologist. The site of the tumor is critical. Tumors of the iliac wing can be resected without much functional loss if the acetabulum can be preserved (Fig. 49-29). Bone grafts are sometimes used to restore the pelvic ring. Similarly tumors involving the pubic rami can be resected and require little reconstruction other than synthetic mesh to prevent herniation of the abdominal contents (Fig. 49-30). The difficult area is the acetabulum. Resection of the acetabulum or other areas of the pelvis that include the acetabulum result in complex reconstruction challenges. Often the best alternative is to leave the hip flail (Fig. 49-31). Significant shortening will occur, but function is better than an amputation even if a major nerve is sacrificed. Attempts at arthrodesis of the proximal femur to the remaining

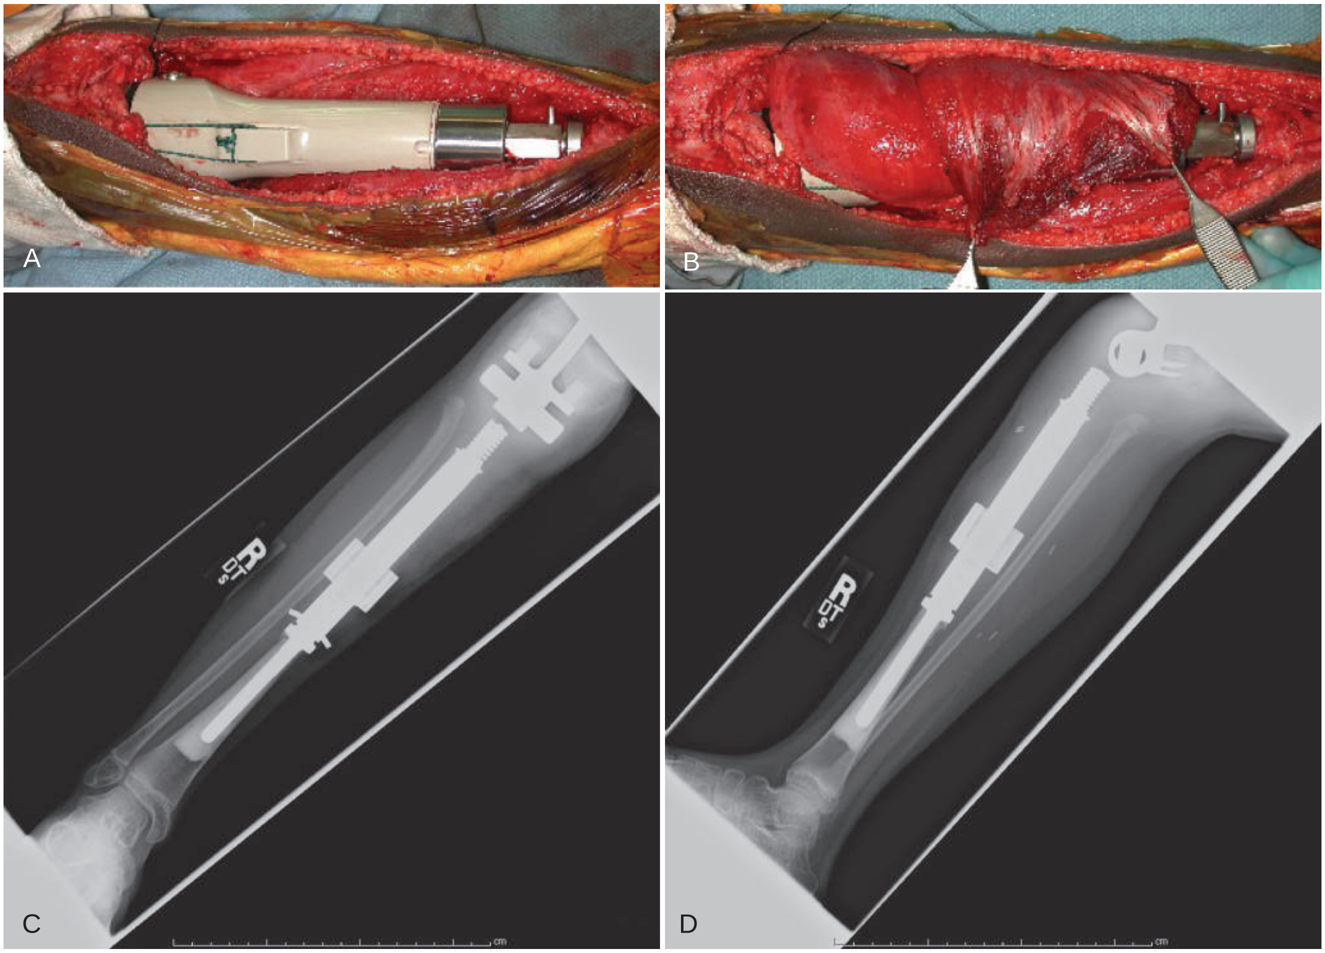

Figure 49-24 **A**, This is an example of an expandable prosthesis for the proximal tibia. The sutures for attachment of the patellar tendon are seen. **B**, The implant has been covered with a gastrocnemius and soleus flap that aid in anchoring of the patellar tendon and wound healing. This particular prosthesis allows lengthening without an operation. **C** and **D**, Anteroposterior and lateral views show the radiographic appearance of the prosthesis in place. The spring mechanism allows for the expansion after an electromagnetic field transiently melts a restraint to expansion.

pelvis can be considered but are very difficult to achieve. Allografts have been used, but are reported to have significant morbidity including a high infection rate and long-term mechanical problems such as fracture.[197-200] Custom metallic replacements have also been used,[201] but they require careful planning and have a high failure rate. All of these considerations are amplified if the adjacent sacrum requires resection as well. The multidisciplinary team and the family must have a careful discussion of the goals, resection options, reconstruction alternatives, and other treatment strategies before these pelvic resections are undertaken. Surgical expertise with the intraoperative and postoperative management of these patients is essential for success.

Proximal Humerus

All attempts should be made to avoid amputation in patients with upper extremity tumors. Unlike the lower extremity, there are no prostheses that replicate the function of the hand. Limb length in the upper extremity is usually not a major concern. A resection of the proximal humerus and scapula en bloc (Tikhoff-Linberg resection) is preferable to a forequarter amputation and is usually possible.[202-207]

For those patients with proximal humeral sarcomas that are amenable to intraarticular resections, reconstruction can be accomplished with metallic prostheses (Fig. 49-32),[158,163,208-211] osteoarticular allografts (Fig. 49-33), or allograft-prosthetic composites.[138,212-214] Function is more a result of whether the deltoid, axillary nerve, and rotator cuff can be preserved. A flail shoulder is superior to an amputation if all these muscles must be resected. For high-grade sarcomas, the deltoid is often resected, but some active motion can be preserved if all or part of the rotator cuff can be preserved. Allografts provide sites for attachment of these motors, but metallic prostheses combined with synthetic materials around the prosthesis and synthetic suture materials can result in active motion as well. Even tumors that require resection of the radial nerve can be reconstructed and the resultant nerve deficit treated either by nerve graft or tendon transfers to restore radial nerve function in the hand. If the joint is involved, an extraarticular resection including the glenoid can be performed. The decision is between the above constructs

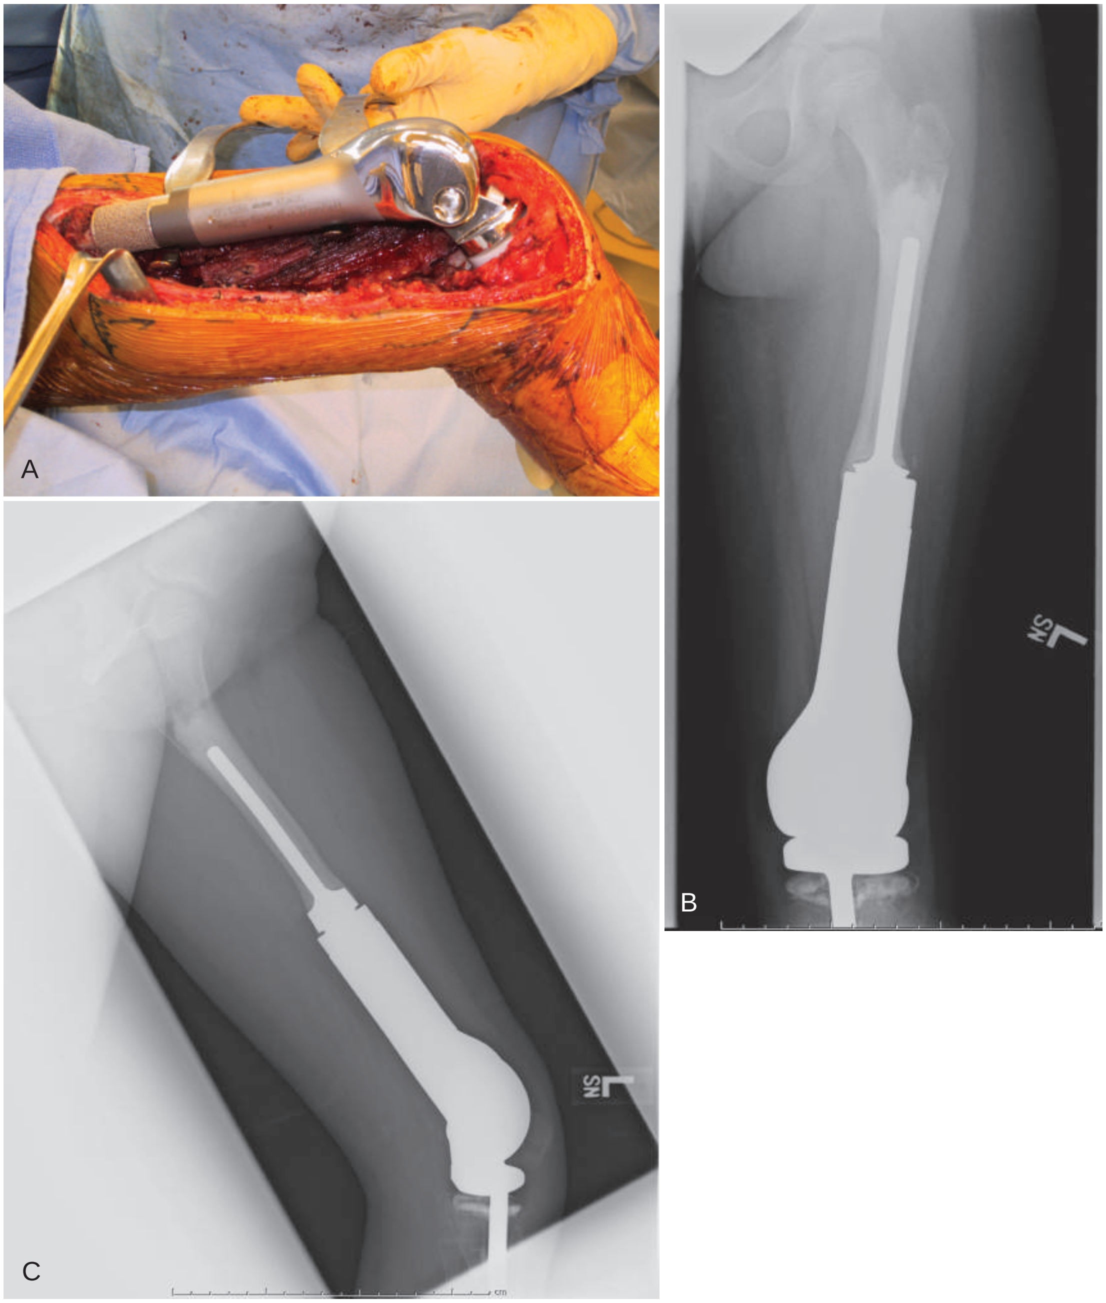

Figure 49-25 **A**, This figure shows the intraoperative appearance of another expandable prosthesis of the distal femur. Figure 49-28 The intraoperative appearance of a modular metallic bipolar prosthesis with sites for sutures to secure the abductors. The rough surface is designed to allow tissue ingrowth with time. Distally, a similar surface allows placement of bone graft to seal the bone-cement interface and retard loosening.

and an arthrodesis using allografts with or without vascularized fibular grafts.[142,212,213,215] The latter allows for a stable shoulder, which is useful in a laborer but is difficult to achieve.

Outcomes

Although the goal of preserving a limb is laudable, and with experience the success rate of restoring functional limbs is improving, limb-sparing procedures are very complex operations. The short- and long-term complications are not trivial. It should also be remembered that young patients with amputations of the lower extremity do quite well with modern prostheses. We are only beginning to assess the quality of life and functional outcomes after these reconstructions, and the tools we have to assess these parameters are limited. The data that exists suggests that the energy cost of walking is better with a metallic prosthesis than an above-knee amputation.[216] A rotationplasty is similar to a below-knee amputation in that regard.[217] Most of the outcome studies report function using the Musculoskeletal Tumor Society rating system that has not been validated and is based on a surgeon assessment. Other outcome tools like the Short Form Health Survey 36 (SF-36) or the Toronto Extremity Salvage Score (TESS) are patient driven and not specific to sarcomas or a rare measure of disability.[218] The data

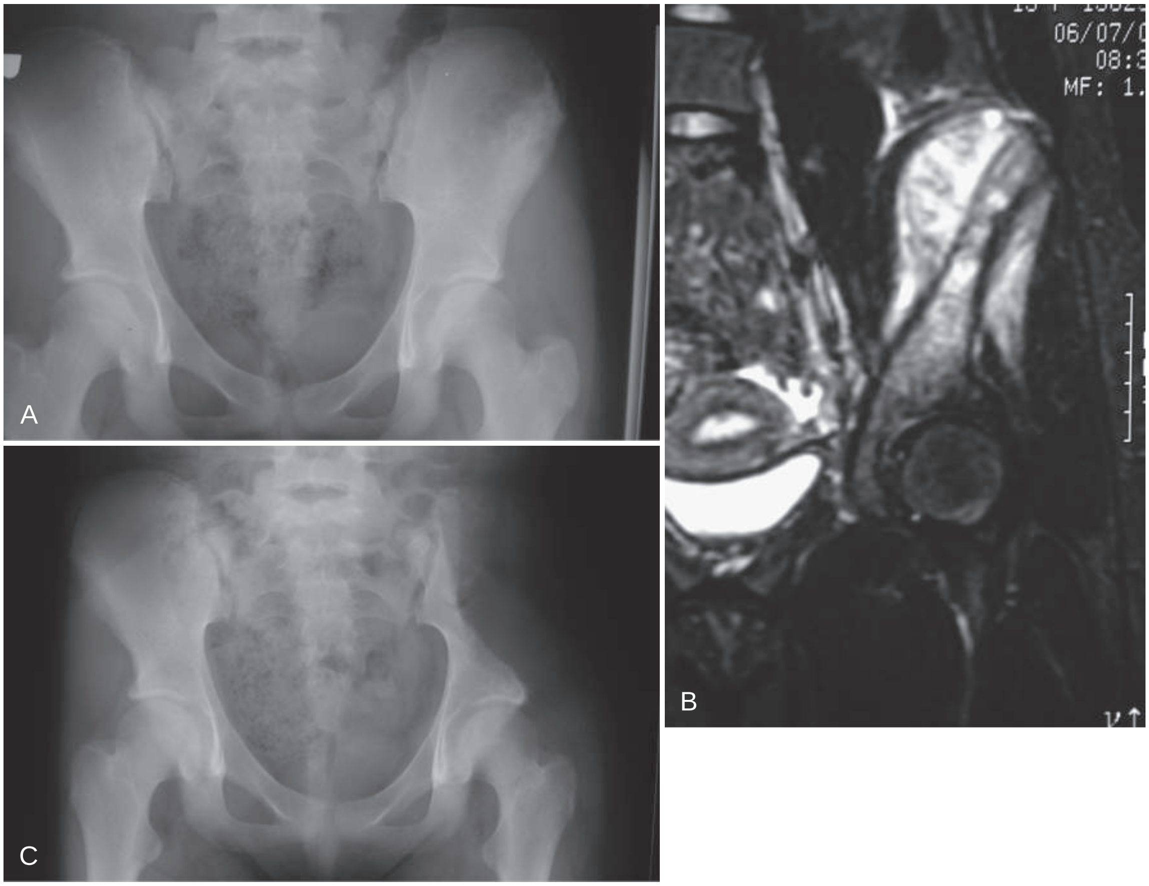

Figure 49-29 **A**, Radiograph of a Ewing sarcoma of the iliac wing. **B**, The magnetic resonance imaging reveals the extent of the soft-tissue mass. **C**, After chemotherapy, the soft-tissue mass was smaller, and resection was possible. The acetabulum was preserved, allowing reasonable function with a mild abductor lurch.

suggest that there is little difference in outcomes and quality of life between amputees and limb-salvage patients and even less between the various types of reconstruction. However, the data are meager, and no controlled studies have been performed. This is an area for further study and development while the reconstruction options and prosthesis continue to evolve. Much progress has been made in the ability to treat pediatric bone sarcomas and to preserve limbs, but better reconstruction options are needed, including future developments in tissue engineering.

MANAGEMENT OF PULMONARY METASTASIS IN PEDIATRIC SOLID TUMORS

The value of the pediatric surgical oncologist in the locoregional control of malignant lesions in children was established well before the advent of chemotherapy or radiotherapy. However, the same cannot be said for the treatment of tumor metastases, especially in the lung. Two excellent reviews of the evolution and disease-specific implementation of pediatric pulmonary metastasectomy have been published.[219,220] The last five decades have produced a rapid expansion in the use of pulmonary metastasectomy for pediatric cancers, but evidence-based proof of its efficacy is limited. This is the result of a general lack of tumor-specific, prospective, randomized clinical trials critically evaluating this therapeutic intervention. Reported studies are primarily from a single institution, retrospective in nature, and often span years to decades and multiple treatment protocols. The studies also generally clump multiple tumors, thereby weakening the strength of any recommendations. Despite these limitations, some general principles and lesion specific recommendations can be made.

The Four Principles

When considering the management of a suspected metastatic pulmonary lesion, four principles must be addressed for each patient. First, the primary tumor diagnosis must

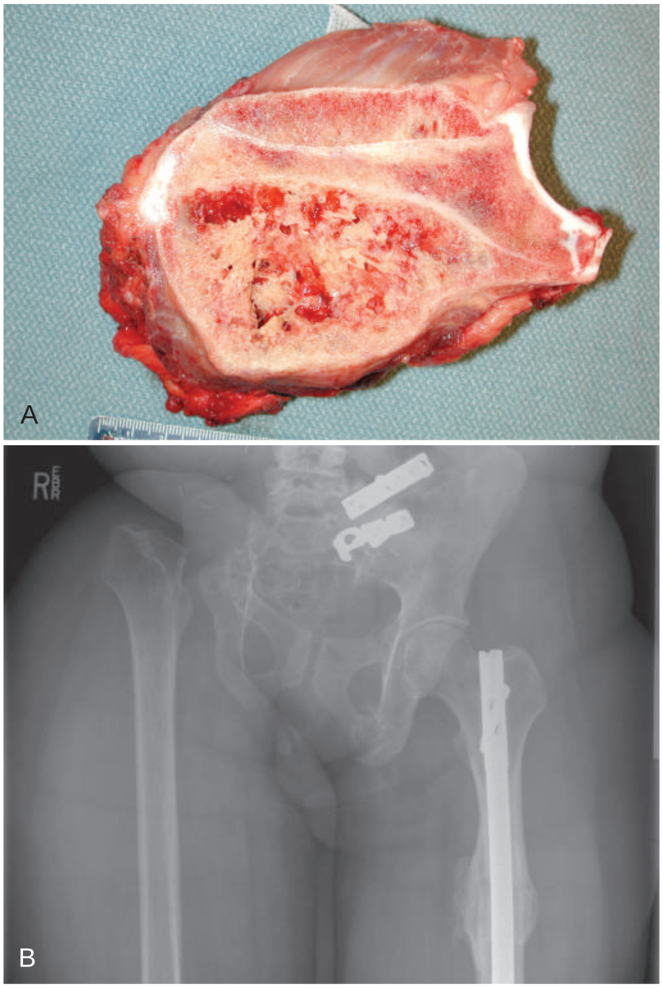

Figure 49-31 **A**, A specimen after resection of the iliac crest including the acetabulum for osteosarcoma (OSA). Function after these procedures is poor but better than an external hemipelvectomy. **B**, The radiograph of another patient more than 20 years after resection of her right ilium and acetabulum for OSA. She has had a closed femoral shortening on the left side to partially balance limb lengths. Despite her disabilities, she works full time and has a family.

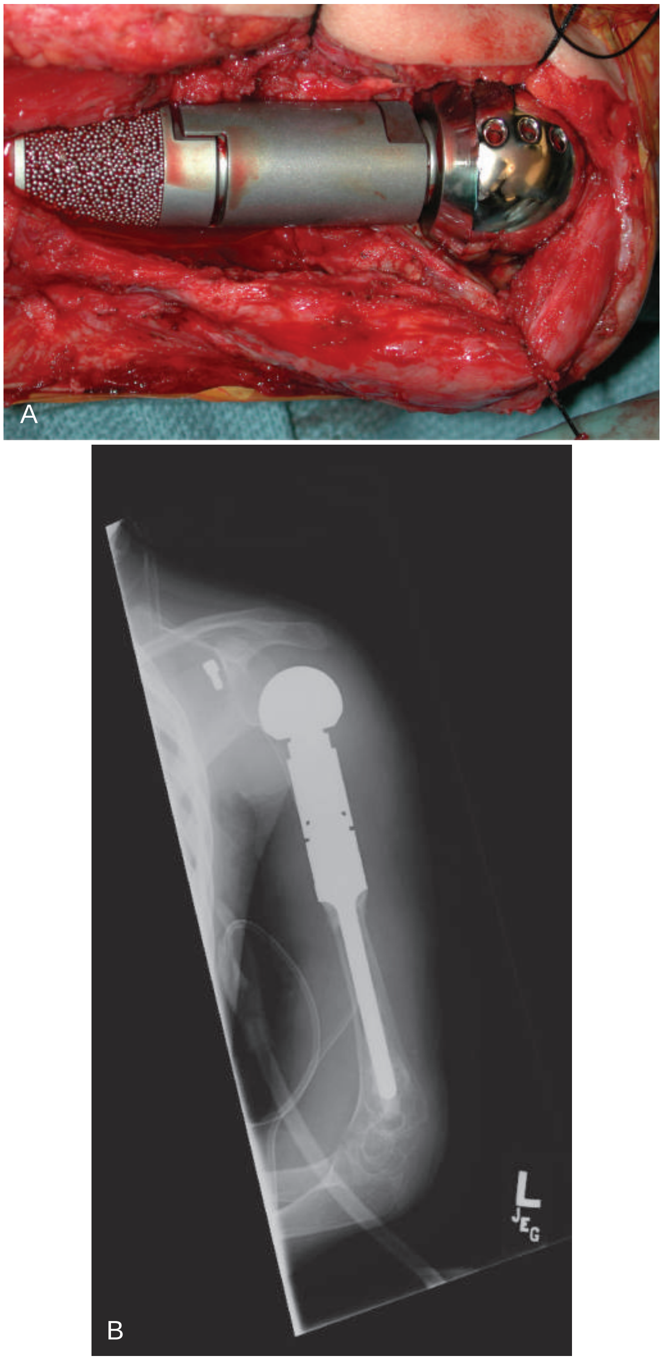

Figure 49-32 **A**, Intraoperative photograph of a metallic prosthesis used to reconstruct a patient with Ewing sarcoma who had a local recurrence after intercalary resection and allograft reconstruction. **B**, A postoperative radiograph of the prosthesis is shown. Active abduction is limited, but she has normal hand and elbow function.

be established. Response of pulmonary lesions to chemotherapy and radiotherapy is linked not only to the primary diagnosis but to the biologic subtype involved (i.e., favorable versus anaplastic Wilms tumor).

Second, the primary tumor must be controlled. A surgeon should not consider pulmonary metastasectomy before achieving local control of the primary lesion. However, biopsy to establish the presence of metastasis is required in some settings, because it determines the intensity of therapy.

Third, the therapeutic benefit to surgical resection must be assessed, and this is clearly dependent on the specific tumor. Ideally, the cancer should be chemoresponsive so as to control residual micrometastases. The lack of effective adjuvant therapy may temper the enthusiasm for pulmonary metastasectomy.

Finally, the extent of the pulmonary resection required to remove all metastatic disease should be assessed. The extent of the resection must be balanced with the therapeutic benefit achieved. An aggressive resection creating pulmonary impairment is difficult to support in the presence of chemotherapy-resistant disease, particularly in the presence of multiple lesions. Some cancers (e.g., OSA, adrenocorticocarcinoma) require an aggressive operative approach to remove all gross evidence of disease because of limited chemotherapy response in an attempt to provide an improved overall and disease-free survival.

Metastasis Localization

Depending on the cancer involved, a combination of radiographic studies and nuclear imaging modalities are used to identify metastases, especially in the lungs. Multidetector CT (MDCT) is the mainstay of identifying pulmonary lesions, and nuclear imaging is used for osseous lesions. More than 80% of lesions greater than or equal to 3 mm can be readily identified with this imaging modality,[221,222] but increasing sensitivity comes with decreasing specificity. Many lesions identified on MDCT may not be

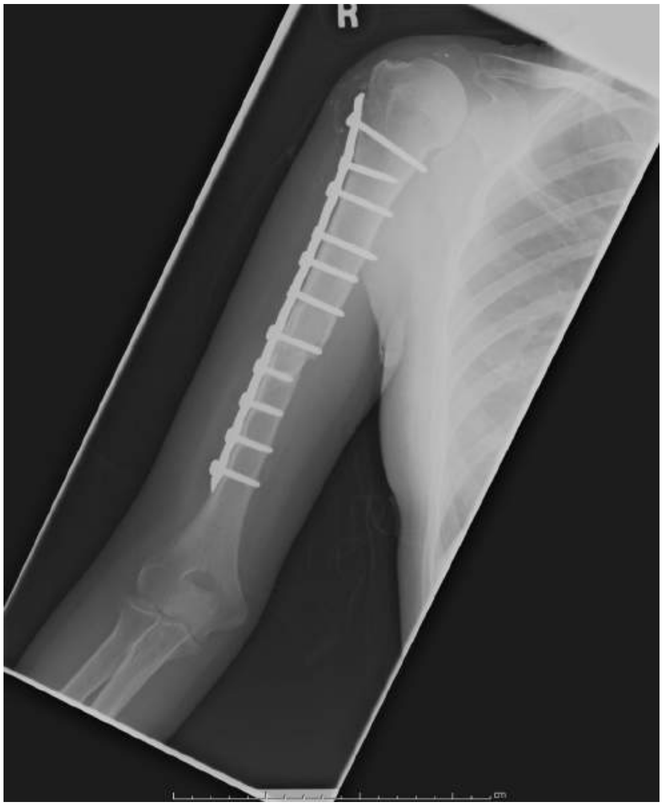

Figure 49-33 A proximal humeral osteoarticular allograft was used to reconstruct an intraarticular resection of the proximal humerus.

malignant. Although the appearance and location of the lesion may help, peripheral lesions that are smooth and well circumscribed are more likely to be malignant; biopsy is required for small lesions. Multiple lesions are also more likely to be malignant than isolated lesions.[223] Beyond this modality, nuclear medicine studies have been used for specific tumors with some success. Nuclear medicine studies exploit the biologic pathways of substrate molecules unique to specific tumors to identify these lesions as "hot spots" on subsequent whole-body scanning. These studies seldom stand alone as the only means to identify metastases, and they routinely act as corollary or confirmatory tests for lesions identified on MDCT. For example, a bone scintigraphy has been used to identify lesions in OSA,[220] but it is only taken up by large and biologically active lesions. Iodine[131] total body scans are routinely used in the evaluation and identification of pulmonary or osseous metastases in differentiated thyroid cancer, and it appears to be very sensitive and specific.[224-231] Finally, whole-body positron emission scanning utilizing fluorodeoxyglucose (18F-FDG PET) has been reported to have a sensitivity of 87% to 89% and a specificity of 100% in sarcomatous[232,233] and carcinomatous[233] pulmonary metastases, but this technique has limited assessment in pediatric primary malignancies, let alone metastases.

Biomarkers may be confirmatory tests for suspicious lesions found on MDCT or nuclear scintigraphy. Examples of tumor types with such markers that are routinely studied are adrenocortical carcinoma, differentiated thyroid carcinoma, germ cell carcinoma, and hepatoblastoma.

Technical Considerations

Pulmonary metastasectomy can be performed safely with minimal morbidity and a mortality rate of less than 1% documented in the International Registry of Lung Metastases.[233] The type of pulmonary resection can be either anatomic or nonanatomic ("wedge") despite early reports to the contrary,[234] but the vast majority of pulmonary metastasectomies performed are wedge resections that remove the lesion with a small rim of normal lung parenchyma (5 to 10 mm). Collective studies document the success of this procedure without the need for a formal lung resection along anatomic boundaries.[223,233, 235,236-238]

The use of MIS approaches for the resection of pulmonary lesions has been described in several studies.[239-244] Additionally, a recent report by Zaman and colleagues[245] analyzed various techniques—finger palpation, intraoperative ultrasound, hook-wire techniques, spiral-wire techniques, and fluoroscopic and/or radio guided detection—that can be used to assist in the localization of subcentimeter pulmonary nodules in conjunction with an MIS approach. Their conclusion was that radio guided techniques are superior to all others, especially finger palpation, which they recommended should be abandoned. MIS alone or in conjunction with other intraoperative localizing procedures has become an established technique except in the case of OSA, in which MDCT scanning has been shown to underestimate the number of lesions and formal thoracotomy has been recommended.[246] A cohort of patients with OSA and unilateral, metachronous pulmonary metastases confirmed by MDCT within 2 years of the primary lesion were found to have occult metastases on the contralateral side in 78% of cases.[247] Therefore staged or sequential bilateral thoracotomies are recommended in patients with OSA by some authors, although this approach has not been shown in a prospective study to prolong either EFS or OS.

Select Pediatric Malignancies

Adrenocortical Carcinoma

Pulmonary metastases from adrenocortical carcinoma should be considered for complete surgical removal, because effective chemotherapy is not available. A recent review of the International Pediatric Adrenocortical Tumor Registry revealed that the mean age of patients at presentation was 3.2 years, and more than 90% of the lesions were functional tumors (84% virilizing).[248] The 5-year EFS was 54%, and the incidence of pulmonary metastases was 7% at presentation. Prognosis was improved for younger patients with completely resected, small (<200 g), early-stage tumors with virilizing symptoms. Separate analysis of the patients with lung metastases could not be performed because of the small number of patients. Isolated case reports in the literature document long-term survival in patients after pulmonary metastasectomy for adrenocortical carcinoma.[249,250] If one examines the adult studies addressing this question, the role for complete tumor excision becomes readily apparent. Kwauk and colleagues examined their series of 24 primarily adult patients with adrenocortical carcinoma and pulmonary metastases.[251] They noted that complete surgical excision of all metastatic disease achieved a 5-year survival rate of 71% versus 0% for those with unresected disease. Though their patient cohort was small and not randomized, they concluded that in the light of ineffective chemotherapy, complete pulmonary metastasectomy was not only indicated but mandatory to achieve long-term survival.

Schulick and colleagues echoed these results and sentiments when analyzing their institution's results with metastatic adrenocortical carcinoma in predominantly adult patients.[252] In fact, not only do they advocate for an initial pulmonary metastasectomy but for repeated resections as well. Some patients in their series had as many as seven resections for recurrent disease. Although this may seem overly aggressive, they note that for every reoperation, the median survival was longer for complete versus incomplete resection groups, which is probably a function of the biology of the tumor involved and anatomic limits of resection as opposed to the operation performed (Fig. 49-34). Furthermore the majority of metastatic resections performed were for pulmonary disease. Thus the data confirm the important role for surgery in the treatment of adrenocortical carcinoma metastatic to the lungs with resectable disease where increased survival and cure can be achieved.

Differentiated Thyroid Cancer

Pulmonary metastases from differentiated thyroid cancer should not be treated by surgical excision except in cases

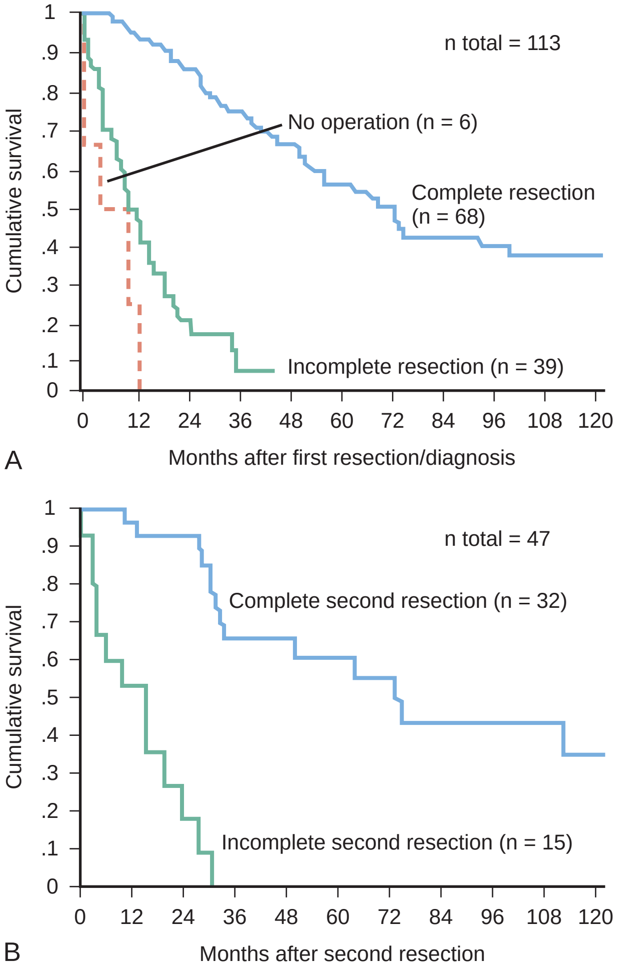

Figure 49-34 **A** and **B**, Disease-specific survival rates for patients undergoing complete versus incomplete primary resections for adrenocortical carcinoma. *(Modified from Schulick RD, Brennan MF: Long-term survival after complete resection and repeat resection in patients with adrenocortical carcinoma.* Ann Surg Oncol *6(8):719–726, 1999.)*

in which there is indecision about the nature of the diagnosis, especially after treatment. Despite the presence of disseminated disease to the lungs, prognosis is still quite good. Unlike skeletal and pleural involvement, patients with pulmonary metastases have mortality rates from 0% to 6%.[226,227,229-231,252] Studies have reported the incidence of pulmonary metastases of 6% to 25%.[227,231,228,229-231] Interestingly, these studies have also documented that pulmonary metastases are very responsive to radioactive iodine treatment. They are seen more often in younger patients and can first appear more than 10 years from the initial diagnosis.

A recent comprehensive review of the treatment of thyroid cancer in children exposed to radiation from the Chernobyl nuclear power station comprises the largest series of pediatric thyroid carcinoma.[231] Seven hundred and forty cases of thyroid cancer occurred in 681 children with direct exposure to the accident. One hundred thirty-one cases (17.7 %) of pulmonary disease were diagnosed by radionuclide scan with a mean presentation of 19 months after the primary diagnosis. Only 2.3% of patients diagnosed had pulmonary metastases that were found on chest radiograph; hence the authors recommended the use of radioactive iodine scanning as the procedure of choice because of its increased sensitivity and specificity. The risk factors for metastatic disease were female gender, a younger age at diagnosis, and the presence of clinical symptoms. Patients were treated with radioactive iodine for their initial pulmonary metastasis. With therapeutic radioactive iodine administration for pulmonary metastases, 28.9% had a complete response (negative nuclear imaging and thyroglobulin <1 ng/mL), 47.7% had a partial but stable response (negative nuclear imaging and thyroglobulin 1 to 10 ng/mL), and 23.4% had a partial response. The 5- and 10-year survival rates were 99.5% and 98.8%, respectively, with only 5 children dying of distant metastases (3 medullary, 1 follicular, and 1 papillary) with a mean follow-up period of 115 months. This study and others document the success of medical therapy. Surgery is required only for diagnosis if the lesions fail to take up iodine.

Germ Cell Tumors (Gonadal)

Pulmonary metastases from gonadal germ cell tumors should be biopsied only if their origin is in question. This tumor is very responsive to chemotherapy, so resection is performed only after treatment if radiographic abnormalities persist. Germ cell tumors comprise a broad range of tumors, 20% of which are malignant.[253] The malignant lesions are chemosensitive, and with the advent of cisplatin-based regimens long-term survival has increased to 90%.[254] However, residual disease after adjuvant therapies may harbor viable tumor,[254-258] with the lung being the most common site of distant metastasis.[255] Synchronous pulmonary metastases are found in 50% of patients with retroperitoneal lymphadenopathy and in 10% of patients without adenopathy.[254] Therefore the role of pulmonary metastasectomy is primarily to define the presence of viable tumor in residual lesions after chemotherapy. This would establish a basis for further therapy. Several groups have examined their data concerning the role and utility of pulmonary metastasectomy.

Cagini and colleagues examined their cohort of 141 patients over a 17-year period with both pulmonary and mediastinal involvement; 51% of patients had isolated pulmonary disease, 24% had pulmonary and mediastinal disease, and 24% had mediastinal disease alone.[254] Roughly, one third of patients had a single lesion, one third had 2 or 3 lesions, and one third had more than 3 lesions. Eighty-seven percent had a complete resection, and histological analysis revealed that 23% of the lesions had only necrosis or fibrosis, 45% had mature teratoma, and 32% were malignant. Biomarker analysis in these patients was not helpful, because 23% of patients with malignant disease had negative biomarkers. A second recurrence occurred in 47% of patients. The overall mortality rate was 19% for the entire group. Actuarial survival after pulmonary metastasectomy was 78% at 5 years, 76% at 10 years, and 66% at 15 years posttreatment. Statistically significant prognostic factors were the pathology of the specimen (complete necrosis or fibrosis of the specimen as opposed to the presence of viable tumor), presence of residual disease (mediastinal disease alone had a better outcome than pulmonary disease with or without mediastinal disease), and the number of resected lesions.

These results were echoed by Liu and colleagues who examined their cohort of 157 patients with isolated pulmonary metastases after chemotherapy over a 28-year period.[254] The majority of patients had multiple lesions (72%), and 89% of patients underwent nonanatomic resections. The mortality rate was 0.6%, and the morbidity rate was 6%. Pathologic analysis revealed viable tumor in 44% of the cohort, 37% of the cohort had a subsequent recurrence of disease in their chest, and 56% of these died. The overall mortality rate was 32%. Statistically significant negative prognostic factors were age older than 25 years, no cisplatin-based chemotherapy, the presence of viable tumor when the lesions were resected posttherapy, and the existence of metastatic disease outside of the thorax or retroperitoneum. The authors conclude that surgery plays a critical role in determining those patients who would benefit from further therapy. These results are also confirmed by other groups,[256-258] but patient selection is an important criteria. Ultimately, surgical salvage using pulmonary metastasectomy is a viable alternative to patients with residual, radiographically identifiable lesions to determine the chemoresponsiveness of these tumors and to provide for an increased long-term survival with complete surgical resection.

Hepatoblastoma

Pulmonary metastases from hepatoblastoma should be treated first with adjuvant chemotherapy, and only then any residual lesions should be resected. Data to support this concept have appeared over the last several decades with an initial report by Black and colleagues.[259] They reported four patients who were long-term survivors, and they stressed the need for complete local control and adjuvant chemotherapy. Furthermore they correlated the need to perform the pulmonary metastasectomy with the patient's α-fetoprotein levels, especially advocating early surgery for those patients with rising titers on appropriate therapy.

Feusner and colleagues[260] representing the CCG published their results, and they confirmed the premises outlined by Black and colleagues. Of their cohort of six patients with pulmonary recurrence, four had a complete remission and three had a survival of more than 5 years. Their approach was to combine adjuvant chemotherapy with aggressive pulmonary resections. Some caution is appropriate, however, when it is recognized that the OS or EFS of patients who have stage-IV disease in hepatoblastoma is 16%, and patients with relapse generally do worse having already received the primary therapies. Beyond these North American results, two reports from the SIOPEL have documented their results with hepatoblastoma and pulmonary metastases. The first report by Perilongo and colleagues[261] in 2000 documented the results of SIOPEL 1: 20% of patients with hepatoblastoma had pulmonary metastases, and they achieved a 5-year EFS rate of only 28%. A sustained remission of 26% of the cohort with metastatic pulmonary lesions was achieved from chemotherapy alone. Schnater and colleagues[90] analyzed the surgical approach in SIOPEL 1 and documented that 41% of patients who had pulmonary metastases were long-term survivors, but the four patients who underwent surgery and chemotherapy to treat their pulmonary metastases were alive at data analysis (minimum of 2.5 years posttreatment). In a nonrandomized study, the apparent difference in outcome may result from selection factors. Their data also suggest that recurrent pulmonary disease could be cured with surgery and chemotherapy as long as there was local control of the tumor. Thus these studies cumulatively support a possible role for pulmonary metastasectomy for hepatoblastoma in selected residual lesions.

Neuroblastoma

Pulmonary metastases from neuroblastoma are rare, and they should not be treated by surgical excision except in cases in which there is indecision about the nature of the lesion, especially after or during treatment. The incidence of pulmonary metastases from neuroblastoma has been reported to occur in fewer than 1% to 23% of cases[262-266]; however, most large studies report rates of 5% or less.[264-266] They can be synchronous or metachronous, and they are usually multiple, bilateral, subcentimeter, and peripheral. Patients with pulmonary metastases from neuroblastoma have a poor prognosis, a high association of unfavorable Shimada histology, *MYCN* amplification, and a lower EFS rate.[265,266] Hence the utility of performing resections except to confirm the diagnosis is not established.

Wilms Tumor

Pulmonary metastases from nephroblastoma should generally not be resected, and suspected lesions should only be biopsied, although some authors[236,267] have advocated for primary pulmonary metastasectomy to spare the effects of radiotherapy on patients.[268] North American centers under the protocols established by the NWTSG have demonstrated the efficacy of chemotherapy and radiotherapy in the treatment of pulmonary metastases over chemotherapy and surgical excision, regardless of pathologic subtype.[269-271] Specifically, Green and colleagues in 1991 examined patients enrolled in NWTSG studies 1 and 3 with pulmonary recurrences. Of the patients meeting study criteria, the resection of pulmonary metastases within 30 days of diagnosis did not affect 4-year survival outcomes in favorable or unfavorable histopathologic cohorts. Furthermore, Green and colleagues[271] reported results from NWTSG-4, in which pulmonary metastasectomy had almost no role in the treatment of patients with stage-IV disease patients. It was performed for residual lesions after chemotherapy and radiotherapy, but it did not affect the OS rates achieved of greater than 75% to 90%. The importance of biopsy for suspicious lesions, especially small lesions (<1 cm) found only on CT was confirmed recently by Erhlich and colleagues,[272] who reviewed the cases of those children enrolled in NWTSG-5. Thirty-three percent of those who received radiotherapy had a prior biopsy that was negative for tumor, and hence they were overtreated. These results were for patients with both isolated and multiple lesions. These studies collectively confirm the general success of combined chemotherapy and radiotherapy in the treatment of pulmonary metastases in nephroblastoma. Whether in fact those children with metastatic disease seen only on MDCT and resolved with chemotherapy need pulmonary radiotherapy remains an unanswered question. Finally, surgical intervention for pulmonary lesions in nephroblastoma should only be utilized to confirm the existence of malignancy in MDCT-defined masses before administering therapy.

Sarcomas

Pulmonary metastases from sarcomatous pediatric tumors should be biopsied at a minimum, and complete resections should be performed depending on the precise histologic subtype. The most comprehensive reports concerning this topic are by Temeck and colleagues from the National Cancer Institute, who published two reports in the 1990s that documented their results with initial[273] and recurrent pulmonary metastasectomies.[274] Their initial report examined 152 patients who underwent 258 thoracotomies over 18 years. The lesions included OSA (50%), nonrhabdomyosarcoma soft-tissue sarcomas (27%), EWS (18%), and rhabdomyosarcoma (3%). Eighty percent of patients had a complete resection, and the cohort had morbidity and mortality rates of approximately 6% and 1.3%, respectively. The highest median survival occurred in the OSA group (3.1 years), and the lowest was in patients with rhabdomyosarcomas (0.4 years). Statistically significant poor prognostic factors included the presence of three or more metastases, a diagnosis other than OSA, and an incomplete resection. Their follow-up study on recurrent lesions further documented the importance of histological subtypes, because no patients with rhabdomyosarcoma were eligible for evaluation. They also documented that CT missed 39% of lesions, 24% of which were found to be malignant, supporting the need for thorough evaluation of the thorax through an open approach. Furthermore they documented a complete resection rate of 77% with 5.6% morbidity rate and a 1% mortality rate. Finally they documented a statistically significant improved survival rate in those patients who underwent complete resections, regardless of the number of recurrences. In fact this survival advantage was eight to 20 times greater depending on the number of recurrences. These data, though encouraging for sarcomas as a whole, must be considered by individual histologic variants. The one sarcomatous variant that may benefit from pulmonary metastasectomy is OSA.

The utility of complete, recurrent pulmonary metastasectomy in OSA was ushered in with the report by Martini and colleagues describing their experience in 1971.[275] They reported a 45% survival rate in patients who had complete pulmonary metastasectomies, which is four times greater than that of chemotherapy alone. Reports from the last decade[†] have not only confirmed these results but clarified the therapeutic approach to pulmonary metastases in OSA. First, OSA should be treated with a multiagent regimen that addresses synchronous pulmonary lesions at the time of local control. Second, pulmonary lesions should undergo repeated complete resections, because this is the best chance for long-term disease-free survival and OS. Third, extirpation of extrapulmonary metastases does not confer the same survival benefits as does pulmonary metastasectomy and is often less feasible, because many of these osseous. Fourth, CT imaging does not identify all pulmonary lesions, and most lesions are not calcified. Therefore staged bilateral thoracotomies are suggested by some for complete evaluation and resection of all pulmonary disease. Fifth, once metachronous lesions have been identified and treated surgically, a majority of patients will have at least one pulmonary recurrence, and most recurrences are within 12 months of the first resection. Therefore continued surveillance and frequent repeat imaging are essential. Finally, though tumor burden was and still is an important prognostic factor in the determination of outcome, several biologic features (e.g., disease-free interval and percentage of tumor necrosis on histopathologic evaluation) have become even more significant in recent reviews. Hence aggressive, repeated complete resection of pulmonary metastases is critical to the successful treatment of patients with OSA.

    Study demonstrates that the energy cost of walking is lower for a patient with a prosthetic knee replacement than with an above knee amputation.

272. Ehrlich PF, Hamilton TE, Grundy P, et al: The value of surgery in directing therapy for patients with Wilms' tumor with pulmonary disease: a report from the National Wilms' Tumor Study Group. National Wilms' Tumor Study 5. *J Pediatr Surg* 41(1):162–167, 2006.

    Study demonstrates the importance of surgical biopsy in patients with pulmonary lesions after therapy for Wilms tumor. It reveals that in some cases the small nodules were not malignant in origin or had no residual evidence of malignant elements posttherapy.

278. La Quaglia MP: Osteosarcoma: specific tumor management and results. *Chest Surg Clin North Am* 8(1):77–95, 1998.

    Summary of the reports demonstrating the efficacy of surgical resection in the treatment of pulmonary metastases in osteogenic sarcoma.

Isolated Extramedullary Relapses
FUTURE DIRECTIONS

The acute leukemias of childhood are rare diseases that collectively represent about 30% of malignancies in children younger than age 15 years.[1] Approximately 3000 new cases of childhood leukemia occur annually in the United States, 80% of which are acute lymphoblastic leukemia (ALL). Between the 1960s and 1990s, the prognosis for children with ALL improved dramatically. With current multiagent chemotherapy regimens, 80% to 90% of children with ALL are long-term relapse-free survivors.[2,3,4] In this chapter, childhood ALL is reviewed with respect to classification, molecular pathogenesis, clinical presentation, laboratory findings, differential diagnosis, treatment strategies, prognosis, and late effects of therapy. Causative and epidemiologic considerations, including the incidence, prevalence, and life span of afflicted individuals, are discussed in Chapter 40. Discussion of the cytogenetic aspects of the leukemias appears in Chapter 45, and the molecular basis of human malignancy is further discussed in Chapter 33. Details concerning the various chemotherapeutic agents are provided in Chapter 46, and myelogenous leukemias and myeloproliferative disorders are discussed in Chapter 51.

CLASSIFICATION

The childhood leukemias can be classified as acute or chronic. *Acute leukemia* is characterized by clonal expansion of immature hematopoietic or lymphoid precursors, whereas *chronic leukemia* refers to conditions characterized by the expansion of mature marrow elements. *Congenital leukemia* refers to leukemias diagnosed within the first 4 weeks of life.

Acute leukemia is characterized by replacement of normal marrow elements with malignant blast cells, relatively undifferentiated cells with diffusely distributed nuclear chromatin, one or more nucleoli, and basophilic cytoplasm. A number of methods exist for characterizing malignant blast cells, including morphology, cytochemistry, and immunophenotype, as well as chromosomal and molecular genetic aberrations. Approximately 80% of cases of childhood acute leukemia are lymphoblastic.

Morphologic and Cytochemical Classification

The production of blast forms is part of the normal maturational sequence of hematopoietic and lymphoid elements. Blast cells are primitive precursors, lacking many of the features of differentiation. Under normal conditions, blast forms constitute fewer than 5% of the nucleated cells of the bone marrow. Blast cells are usually not observed in the peripheral blood, except during periods of profound overproduction of blood cells in response to infection or bleeding or from bone marrow invasion by granulomas, fibrosis, or tumor cells (leukoerythroblastosis). Leukemic blast cells can be difficult to distinguish morphologically from normal, nonmalignant blasts, although the finding of more than 5% blast forms in the marrow, or the presence of blast cells in the peripheral blood, should raise the suspicion of leukemia. In acute leukemia, patients often present with a marrow that is almost fully replaced by blast forms.

Once the diagnosis of leukemia is made, it is sometimes difficult to differentiate a lymphoid from a myeloid blast. The morphologic characteristics of lymphoblasts are shown in Figure 50-1. Wright-Giemsa–stained lymphoblasts have smooth, homogeneous nuclear material with indistinct nucleoli and only a small rim of light blue–staining cytoplasm, generally without granules. In contrast, myeloblasts differ from lymphoblasts in that the former have a lower nuclear-to-cytoplasmic ratio, more finely developed nuclear chromatin, and more distinct punched-out nucleoli. Cytoplasmic granules are often present in myeloblasts, and the detection of eosinophilic Auer rods is pathognomonic. However, small myeloblasts may be confused with lymphoblasts morphologically, although they can usually be distinguished by flow cytometric or cytochemical studies.

A standardized morphologic classification system devised by the French-American-British (FAB) Cooperative Working Group is generally used to categorize the appearance of leukemic blasts.[5] In this system, ALL is subdivided into three morphologic categories: L1, L2, and L3 (see Fig. 50-1). L1 is the most common subtype, observed in about 90% of cases of childhood ALL. L1 lymphoblasts are small cells characterized by a high nuclear-to-cytoplasmic ratio. The pale blue cytoplasm is scanty and limited to a small portion of the perimeter of the cell. The cells have indistinct nucleoli and nuclear membranes that vary from round to clefted. Cells in the L2 category, found in 5% to 15% of pediatric cases, are larger than those classified as L1, show marked variability in size, and have prominent nucleoli and more abundant cytoplasm. They may be difficult to distinguish morphologically from the M1 variant of myeloid leukemia, and thus flow cytometric analysis of cell surface markers is essential to differentiate ALL from acute myelogenous leukemia (AML). L1 and L2 lymphoblasts do not differ significantly in terms of cell surface markers, genetic abnormalities, or prognosis.[6,7] Only 1% to 2% of

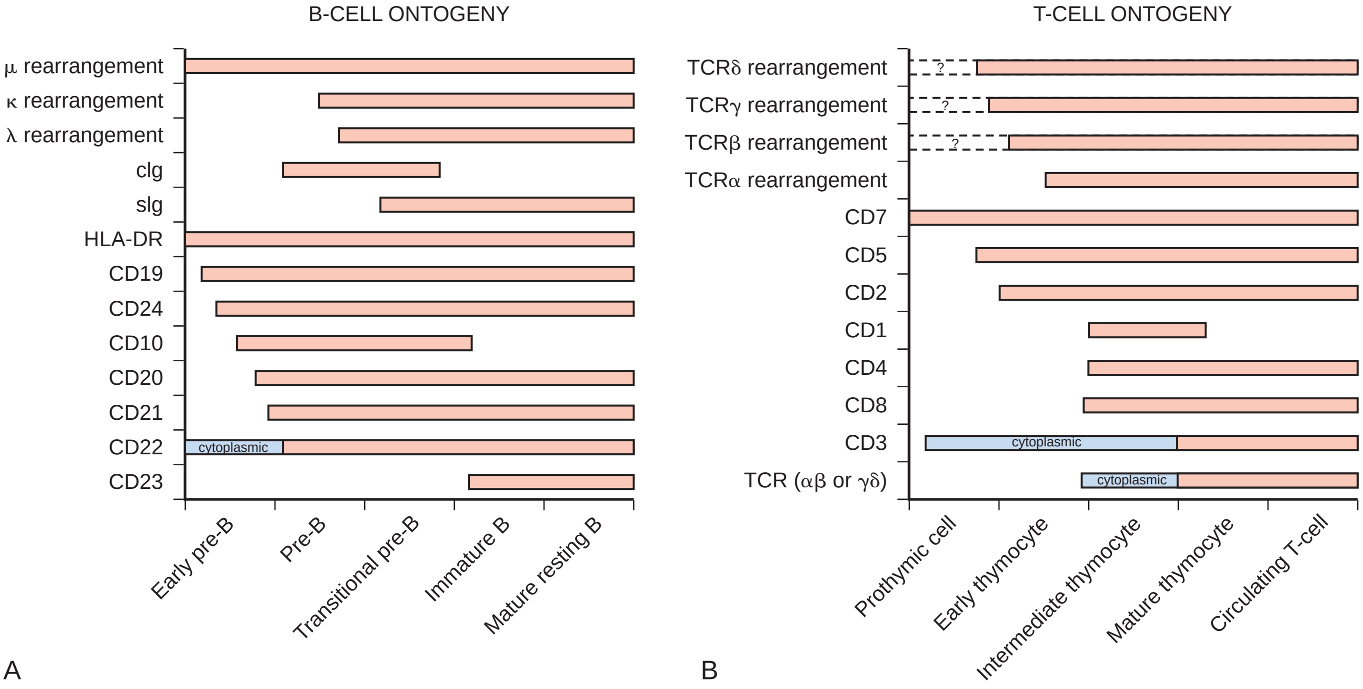

Figure 50-2 Schematic representation of human lymphoid differentiation. **A,** Hypothetical schema of marker expression and gene rearrangement during normal B-cell ontogeny. **B,** Hypothetical schema of marker expression and gene rearrangement during normal T-cell ontogeny. *(Modified from Pui CH, Behm FG, Crist WM: Clinical and biologic relevance of immunologic marker studies in childhood acute lymphoblastic leukemia.* Blood *82:343–362, 1993.)*

ALL pediatric patients have L3 lymphoblasts, which appear identical to Burkitt lymphoma cells, with deeply basophilic cytoplasm and prominent cytoplasmic vacuolization. L3 morphology is almost always associated with a mature B-cell phenotype (including expression of surface immunoglobulin) and translocations involving the *MYC* gene on chromosome 8; patients with these characteristics should be treated with regimens for advanced-stage Burkitt lymphoma rather than ALL.[8,9] Other morphologic variants of ALL, including ALL with hand mirror cells or granules, have been described but do not appear to have prognostic significance.[7]

Various cytochemical stains can distinguish ALL from AML. In approximately 80% of cases of ALL, lymphoblasts react positively with periodic acid–Schiff (PAS), which stains cytoplasmic glycogen.[10] Myeloid-specific stains, such as myeloperoxidase, specific and nonspecific esterase, and Sudan black (a cytoplasmic lipid stain), are usually negative in ALL. In contrast, myeloblasts are myeloperoxidase positive in 75% of patients. Terminal deoxynucleotidyl transferase (TdT), an enzyme that catalyzes the polymerization of deoxynucleoside monophosphates into a single-strand DNA primer, can be demonstrated in most cases of ALL but is rarely present in cases of myeloid leukemia.

Immunophenotype

ALL is subcategorized based on the expression of lineage- and maturation-specific antigens present on the cell surface and in the cytoplasm of lymphoblasts. In addition, immunophenotypic studies of lymphoblasts have provided important insights into the differentiation and maturation of normal B and T lymphocytes. Because the leukemic blast represents the neoplastic expansion of a lymphoid progenitor cell, many phenotypic and genotypic features of the lymphoblast mimic those of the normal lymphoid cell counterpart of specific lineage and maturational stage.[11] Figure 50-2 depicts a schematic overview of lymphoid cell differentiation.[12]

Based on reactivity with a panel of lineage-associated antibodies, ALL has been subclassified into three broad categories: B-precursor cell, mature B cell, and T cell. The immunophenotypic subsets are associated with distinctive clinical features (Table 50-1).[13]

B-Precursor Cell ALL

The B-precursor cell phenotype is present in 80% to 85% of children with ALL. These leukemia cells are characterized by reactivity with monoclonal antibodies specific for B-cell–associated antigens (e.g., CD9, CD19, CD22, and CD79a) and are distinguished from mature B-cell ALL by the absence of surface immunoglobulin. In the vast majority (80% to 90%) of B-precursor cell ALL, the cells express CD10, also known as the common ALL antigen (CALLA).

Over 90% of cases of B-precursor cell ALL have evidence of immunoglobulin gene rearrangements, predominantly involving the immunoglobulin heavy chain (IgH).[14] Of note, T-cell receptor (TCR) gene rearrangements also may be observed in B-precursor cell ALL and IgH gene rearrangements have been observed in T-cell ALL.[15] These leukemia-specific clonal IgH and TCR gene

TABLE 50-1 Correlation of Immunophenotype with Clinical Characteristics

Parameter	Early Pro–B Cell, CD10–	Early B-Precursor Cell, CD10+	Pre–B Cell (cIgM+)	T Cell
No. of patients	52	635	156	124
Gender (% male)	39%	53%	50%	75%

rearrangements have been used to quantify submicroscopic levels of residual leukemia in patients using polymerase chain reaction (PCR)-based assays.[15]

The presence of intracytoplasmic immunoglobulin (cIg) and various cell surface markers has been used to distinguish different subsets of B-precursor cell ALL based on their level of differentiation. These subsets include pro-B ALL (3% to 4% of pediatric patients), early pre-B ALL (60% to 70% of pediatric patients), and pre-B ALL (20% to 30% of pediatric patients):[16]

- Pro–B-cell ALL, believed to be derived from a very immature B-cell precursor, is characterized by CD10-negative immunophenotype and the absence of cIg. It is most frequently observed in infants with ALL, especially those with abnormalities involving chromosome 11q23 (*MLL* [also known as *KMT2A*] gene locus).[17,18]
- Early pre–B-cell ALL is the most common subtype of B-precursor cell ALL in children. It is believed to be derived from a more mature B-cell precursor than pro-B ALL. Early pre–B cells frequently express CD10 but still lack cIg. CD10 (CALLA)-positive leukemias without cytoplasmic immunoglobulin are also referred to as common ALL (c-ALL).[19]
- Pre–B-cell ALL is characterized by the presence of cIg.[20] It is believed to derive from an intermediate B-precursor cell, more mature than those lacking cIg (early pre–B cells) but not as mature as those with surface immunoglobulin (mature B cells). Like early pre–B cells, pre–B lymphoblasts typically express CD10 and human leukocyte antigen (HLA)-DR. Approximately 25% of cases of pre–B-cell (cIg+) ALL have the chromosomal translocation t(1;19)(q23;p13), which fuses the *TFPT* (formerly *E2A*) gene on chromosome 19 with the *PBX1* gene on chromosome 1.[20] This translocation is observed in only 1% of cases of early pre-B (or common) ALL.

Mature B-Cell ALL

Mature B-cell ALL accounts for 1% to 2% of childhood ALL cases.[21] It is characterized by the presence of surface immunoglobulin, most often IgM, which is monoclonal for κ or λ light chains. The cells generally express other B-cell antigens, including CD19, CD20, and HLA-DR. Morphologically, the blasts tend to be classified as FAB L3, with intensely staining cytoplasmic basophilia similar to that of erythroblasts. Cases of mature B-cell ALL without L3 morphologic features have been reported but are rare.[22] Almost all cases of mature B-cell ALL are associated with one of three nonrandom chromosomal translocations—t(8;14)(q24;q32) or, less commonly, t(2;8)(p12;q24) or t(8;22)(q24;q11).[23] The chromosomal breakpoints involve the *MYC* oncogene on chromosome 8 and the genes for the IgH (chromosome 14), κ light chain (chromosome 2), or λ light chain (chromosome 22). Mature B-cell ALL is clinically indistinguishable from disseminated Burkitt lymphoma and is much more successfully treated with regimens used for that disease than when treated with conventional childhood ALL therapy.[8,9]

T-Cell ALL

The T-cell immunophenotype is present in 10% to 15% of children with ALL.[24] Compared with B-precursor cell ALL, T-cell ALL is more frequently associated with older age at diagnosis, higher presenting leukocyte counts, and bulky extramedullary disease (including lymphadenopathy, hepatosplenomegaly, overt central nervous system [CNS] leukemia, and an anterior mediastinal thymic mass).[16] Historically, patients with T-cell ALL had an inferior outcome compared with those with B-precursor cell ALL, although this prognostic difference is not observed when more intensive regimens are used.[25] However, the time period in which relapses occur differs between the two immunophenotypic subtypes, with earlier relapses observed more frequently in T-cell ALL.[25]

T-cell ALL can be subclassified using monoclonal antibodies that recognize surface antigens expressed during discrete stages of normal T-cell development.[26] Most of the phenotypically defined subsets of T-cell ALL have limited clinical relevance.[27,28] However, gene expression profile studies have identified a biologically distinctive subset of T-cell ALL that, in retrospective analysis, was associated with a high risk for treatment failure.[29] These patients were noted to have a distinctive “early T-cell precursor” phenotype consisting of weak expression of CD5 and coexpression of stem cell or myeloid markers.[29] Similarly, another retrospective study using array comparative genomic hybridization (CGH) and quantitative DNA-PCR techniques identified the absence of V(D)J recombination at the TCRγ locus, a feature that is characteristic of early T-cell precursor cells, as a predictor of early treatment failure in patients with T-cell ALL.[30] Thus, T-cell ALL patients with features of development arrest at the earliest stages of T-cell development appear to have an inferior outcome.

Myeloid Antigen Coexpression

In some instances, individual leukemic cells simultaneously express lymphoid and myeloid surface antigens. Up to 20% of cases of ALL (i.e., with lymphoid surface antigen predominance) also coexpress myeloid antigens.[31,32] Myeloid antigen coexpression is associated with young age at diagnosis (<12 months), pro–B-cell (CD10−) immunophenotype, and certain chromosomal abnormalities, such as rearrangements of chromosome 11q23 (frequently observed in infants with ALL), the Philadelphia (Ph) chromosome [t(9;22)], and the *ETV6-RUNX1* [t(12;21)] fusion.[33-35] Older studies suggested that patients with biphenotypic ALL had a worse prognosis,[36] but more recent reports have indicated that myeloid antigen coexpression lacks independent prognostic significance.[31-33] Cases of ALL with myeloid antigen coexpression should be distinguished from leukemia of ambiguous lineage, an uncommon entity in which the predominant lineage (lymphoid or myeloid) cannot be determined by immunophenotype and histochemistry. The World Health Organization classification system requires that cells express myeloperoxidase or evidence of monocytic differentiation, along with either T-cell antigen CD3 (cytoplasmic or surface) or B-cell surface antigens (CD19, CD79a, CD22, and CD10).[37]

MOLECULAR PATHOGENESIS

Lymphocytes arise from hematopoietic stem cells through a series of proliferation and differentiation steps that result in the formation of mature B or T lymphocytes, each expressing a specific immunoglobulin or TCR capable of responding to a narrow range of foreign antigens. The development of a fully competent adaptive immune system is dependent on the generation of a population of mature B and T lymphocytes with extraordinary diversity in antigen specificity, which collectively provide the ability to mount an effective immune response against a broad range of pathogens. This diversity in antigen receptor specificity is achieved through an elaborate process of somatic mutagenesis, including V(D)J recombination and somatic hypermutation, designed to introduce unique variations in the immunoglobulin or TCR gene structure of each individual developing lymphocyte. Despite their carefully regulated nature, these programmed mechanisms of somatic mutagenesis can go awry and introduce somatic mutations at other genomic loci. Mutations in oncogenes or tumor suppressors acquired during lymphocyte development can result in the aberrant proliferation and differentiation arrest that are characteristic of ALL.

Although a comprehensive review of the molecular pathogenesis of ALL is beyond the scope of this chapter, we highlight here select molecular lesions that have proven particularly informative to our understanding of the pathobiology of ALL and review in more detail the molecular pathogenesis of three particularly high-risk subtypes of ALL: BCR-ABL, hypodiploid, and early T-cell progenitor ALL.

Transcriptional Regulators

ETV6-RUNX1 Fusion Genes in B-Precursor Cell ALL

In 20% to 25% of childhood ALL cases a cryptic t(12;21) translocation results in expression of a fusion *ETV6-RUNX1* (also known as *TEL-AML1*) translocation.[38] *ETV6* and *RUNX1* are transcription factors that are each required for normal hematopoiesis, and both are involved in other leukemia-related translocations. The t(12;21) translocation results in the fusion of the HLH domain of *ETV6* to almost all of *RUNX1*. The mechanisms through which *ETV6-RUNX1* fusions drive leukemogenesis remain incompletely understood, but recent work has shown that expression of this fusion oncoprotein in hematopoietic stem cells markedly increases their numbers and promotes their transformation after chemical mutagenesis.[39] Interestingly, *ETV6-RUNX1* translocations can often be detected in prenatal blood specimens collected from children who went on to develop *ETV6-RUNX1*–rearranged ALL many years later, indicating that it is likely the initiating mutation in ALL.[40] However, this translocation is not sufficient for leukemogenesis because the incidence of detectable *ETV6-RUNX1* fusions in normal neonatal blood is 100-fold greater than the incidence of leukemia with this translocation.[41] Several studies have shown that the presence of an *ETV6-RUNX1* translocation is associated with a favorable prognosis in childhood ALL.[42,43] Indeed, *ETV6-RUNX1* expression is associated with decreased expression of the *ABCB1* (also known as *MDR1*) multidrug resistance gene and of genes involved in purine metabolism, which may explain the particular sensitivity of these cases to mercaptopurine and methotrexate.[44,45]

MLL Fusion Genes in B-Precursor Cell ALL

Chromosomal translocations resulting in the fusion of the amino-terminus (N-terminus) of the *MLL* gene on 11q23 to the carboxy-terminus (C-terminus) of one of more than 60 different translocations partners occur in 70% of infant ALL, in 10% of AML, and in the majority of secondary AML cases that are induced by prior treatment with topoisomerase II inhibitors.[46] The presence of *MLL* translocations is associated with inferior outcomes despite aggressive chemotherapy in ALL, as discussed later in this chapter. *MLL* is the human ortholog of *Drosophila trithorax*, which positively regulates expression of multiple genes of the *HOXA* cluster and acts antagonistically to the polycomb group of proteins. The breakpoints of *MLL* translocations cluster between exons 5 and 11 of *MLL*, resulting in expression of fusion oncoproteins that retain the N-terminal domains of the protein that bind DNA in a sequence-nonspecific manner, whereas the C-terminal domains of MLL that mediate association of the wild-type protein with its endogenous chromatin modification complex and its Histone H3 lysine-4–specific *N*-methyltransferase activity are invariably lost.[47] Instead, the C-terminus of MLL fusion oncoproteins is provided by one of more than 60 different translocation partners, with common translocations such as the t(4;11), t(9;11), and t(11;19)(q23;p13.3) resulting in the in-frame fusion of *MLL* to the C-terminal domains of *AF4* (also known as *AFF1*), *AF9* (also known as *MLLT3*), and *ENL* (also known as *MLLT1*), respectively.[48,49] Expression of MLL fusion oncoproteins in murine hematopoietic precursors induces leukemia,[50-54] an effect that is dependent on MLL fusion oncoprotein–driven overexpression of several genes of the *HOXA* cluster.[55,56]

Until recently, the mechanism through which the C-terminal fusion partners of MLL contributed to leukemogenesis was unclear, because there were no apparent sequence similarities between the fusion partners involved. However, recent work has shown that several MLL translocation partners are functionally linked through their association in protein complexes that regulate transcriptional elongation.[47] MLL fusion oncoproteins bind at least three distinct complexes, including the polymerase-associated factor complex, the positive transcription elongator factor (pTEFb) complex, and the DOT1L histone methyltransferase complex.[57] The DOT1L methyltransferase is required for the maintenance of MLL-driven leukemias but appears to be less important for normal hematopoiesis, thus suggesting a therapeutic window for targeting DOT1L in MLL-rearranged ALL.[58-62] Indeed, a small molecule DOT1L inhibitor has recently been developed and demonstrates promising preclinical activity in murine models of MLL-rearranged leukemia, raising the possibility that such a therapeutic strategy could improve the prognosis for patients with MLL-rearranged ALL.[63]

MYC Translocations in Mature B-Cell ALL

Chromosome translocations that place the coding region of the *MYC* protooncogene under the control of gene regulatory elements of one of the immunoglobulin receptor genes, such as the t(8;14), t(2;8) or t(8;22), lead to aberrant overexpression of the *MYC* oncogenic transcription factor. *MYC* overexpression is potently oncogenic in a wide range of experimental systems. Although MYC has long been believed to be a traditional transcription factor that regulates a specific set of target genes, recent work has revealed that MYC accumulates at the promoters of essentially all transcriptionally active genes and acts as a nonlinear amplifier of existing gene expression programs.[64,65] Thus, rather than inducing expression of a specific gene expression program, these findings suggest that MYC instead acts to lock a cell's gene expression program into its existing form, which presumably can be oncogenic when it occurs in a cell that is in a highly proliferative state that normally should be transient. *MYC* translocations are characteristically found in mature B-cell leukemia, which is best considered a disseminated form of Burkitt lymphoma that responds poorly to standard ALL therapy. Outcomes for these patients are much improved with treatment regimens specifically designed for high-grade B-cell non-Hodgkin lymphomas.[8,9]

Activating *NOTCH1* Mutations in T-Cell ALL

NOTCH1 encodes an unusual cell surface receptor that, on activation by ligand binding to its extracellular domain, undergoes two distinct proteolytic cleavage events, culminating in release of the intracellular domain of NOTCH1 (ICN) into the cytoplasm. The ICN protein subsequently translocates to the nucleus, where it functions as a transcription factor that generally activates expression of its targets.[66] NOTCH1 is required at multiple stages of T-cell development, and its ectopic activation in murine T-cell progenitors is highly leukemogenic.[66-69] Although NOTCH1 can be activated by chromosomal translocations in very rare cases of T-cell ALL,[70] more than 50% of T-cell ALL cases harbor activating *NOTCH1* mutations, and these occur in all of the molecular subtypes of T-cell ALL.[71] Activating *NOTCH1* mutations typically occur either as missense mutations in the heterodimerization domain, where they promote ligand-independent proteolytic activation of the ICN domain, or as truncating or frameshift mutations in the C-terminal PEST domain of ICN, which lead to ICN protein accumulation as a result of impaired proteasomal degradation.[71,72] The pathogenic role of *NOTCH1* in T-cell ALL is mediated largely by its role as a transcriptional activator of two key downstream targets, *MYC* and *HES1*.[66,73-75]

One of the key proteolytic cleavage events required for NOTCH1 activation is mediated by the γ-secretase complex. Treatment of NOTCH1-mutant T-cell ALL cell lines with γ-secretase inhibitors leads to modest reductions in cell proliferation in a subset of cell lines,[71,76] but a number of NOTCH1-mutant T-cell ALL cell lines fail to respond to these inhibitors. The mechanisms of resistance to NOTCH1 inhibition have been an area of intense investigation, and recent work has revealed that inactivation of the *FBXW7* tumor suppressor, an E3 ubiquitin ligase that targets both ICN and *MYC* for proteasomal degradation, is one mechanism of resistance to γ-secretase inhibitors.[77,78] Additionally, resistance to inhibition of NOTCH1 or its downstream target *MYC* can be mediated by PTEN inactivation and resultant AKT activation in T-cell ALL, thus suggesting the potential therapeutic utility of AKT pathway inhibitors as a strategy to reverse resistance to γ-secretase inhibitor.[79,80] Moreover, glucocorticoid resistance in T-cell ALL has been shown to be reversible by γ-secretase inhibitors, and it appears that glucocorticoid therapy can ameliorate the intestinal toxicity of γ-secretase inhibitors.[81] Taken together, these findings provide a compelling rationale for clinical trials combining glucocorticoids with small molecule inhibitors of NOTCH1 and AKT.

Growth Factor Signaling

Cytokine Receptor Signaling

Cytokine receptor signaling plays key roles in normal lymphocyte development, with inactivating mutations in key cytokine receptor subunits (e.g., interleukin-2 receptor γ [*IL2RG*] and interleukin-7 receptor [*IL7R*]) or their downstream effector kinases (e.g., Janus kinase-3 [*JAK3*]), resulting in severe lymphopenia and the lack of a functional adaptive immune system characteristic of severe combined immunodeficiency. Conversely, aberrant activation of cytokine receptor signaling has recently been implicated in the molecular pathogenesis of ALL.

Cytokine receptor–like factor 2 *(CRLF2)* encodes a cytokine receptor subunit that heterodimerizes with IL7R to form the receptor for the cytokine TSLP (thymic stromal lymphopoietin), which is a proinflammatory cytokine secreted by endothelial cells that drives lymphocyte proliferation.[82] *CRLF2* rearrangements leading to aberrant overexpression have recently been described in B-precursor cell ALL, typically as a result of an intrachromosomal deletion leading to a *P2RY8-CRLF2* fusion, or translocations of the IgH locus to *CRLF2*.[83-85] *CRLF2* rearrangements are found in 5% to 10% of B-precursor cell ALL cases but in more than 50% of patients with Down syndrome–associated ALL, strongly suggesting that these collaborate with trisomy 21 in B-lymphoblast transformation. *CRLF2* rearrangements are often associated with activating mutations of Janus kinase 2 *(JAK2)*, and CRLF2 overexpression and mutated JAK2 cooperate to induce cytokine-independent growth to Ba/F3 pro-B cells.

IL7R encodes a cytokine receptor subunit that can heterodimerize with the IL2Rγ (the common γc chain) to form IL7R, or with CRLF2 to form the TSLP receptor. Recent work has identified activating IL7Rα point mutations in 9% of cases of T-cell ALL, as well as in the "BCR-ABL–like" subset of B-precursor cell ALL (discussed in more detail later).[86,87] Interestingly, most of these mutations result in the introduction of a novel cysteine residue into the extracellular domain of IL7Rα, and aberrant signaling results because disulfide bond formation between these mutant cysteines can allow mutant IL7Rα proteins to aberrantly dimerize, leading to activation of downstream signaling pathways independent of ligand or of the common γc chain.[86,87] The potential therapeutic utility of targeting aberrant oncogenic signaling downstream of mutationally activated cytokine receptors is an area of active investigation.

PTEN and the *PI3K-AKT* Axis

The *PI3K-AKT* oncogenic pathway, which is negatively regulated by the *PTEN* tumor suppressor, mediates prosurvival and proliferative signaling downstream of activated growth factor receptors and is aberrantly activated in a broad range of human cancer subtypes.[88] Recent work has revealed that nearly half of T-cell ALL cases harbor mutational activation of oncogenic signaling through this pathway, most often as a result of truncating mutations or deletions of the *PTEN* tumor suppressor, but activating mutations of *PI3K* and *AKT* genes also occur.[79,89-91] *PTEN* deletions are a strong predictor of early treatment failure in T-ALL cases[86,89] and *PTEN* inactivation has been shown to induce resistance to *NOTCH1* or *MYC* inhibition in zebrafish and murine models of T-cell ALL.[79,80] These findings highlight the potential application of small molecule inhibitors of the *PI3K-AKT* pathway for high-risk T-cell ALL.

Molecular Pathogenesis of Select High-Risk Subtypes

BCR-ABL and *BCR-ABL*–like ALL

The discovery of the Ph chromosome, which arises from the t(9;22)(q34;q11) translocation resulting in expression of a BCR-ABL fusion oncoprotein, was a major milestone in molecular oncogenesis that provided compelling support for the hypothesis, first put forth by Boveri in 1914, that cancer arises due to a genetic lesion in a single cell, resulting in outgrowth of a clonal population.[92,93] *BCR-ABL* translocations are pathognomonic of chronic myeloid leukemia and are also found in 4% to 5% of childhood and 25% of adult cases of B-precursor cell ALL.[38] The translocation underlying formation of the Ph chromosome results in expression of a BCR-ABL fusion oncoprotein with constitutively active tyrosine kinase activity, which transforms cells at least in part due to activation of the RAS-MAPK pathway, PI3K, and JUN-kinase pathways.[94] Although historically associated with an extremely poor prognosis, hematopoietic stem cell transplantation (HSCT) proved to be the first highly effective therapeutic modality for this high-risk subtype of ALL.[95] Additionally, the development of imatinib mesylate, a small molecule inhibitor of oncogenic signaling by the BCR-ABL kinase, has opened novel therapeutic opportunities for the management of Ph chromosome–positive ALL. Although single-agent therapy with imatinib leads to rapid development of resistance in Ph chromosome–positive ALL, pilot trials of the combination of conventional chemotherapy with imatinib or other tyrosine kinase inhibitors have been promising.[96,97]

Although the poor prognosis of BCR-ABL ALL was traditionally believed to be due to expression of the BCR-ABL oncoprotein, recent work has shown that this subtype of ALL is also characterized by inactivation of the DNA-binding protein Ikaros, which is encoded by the *IKZF1* gene.[98] *IKZF1* deletions have been identified in up to 15% of BCR-ABL–negative pediatric ALL cases and have been shown to be an independent predictor of adverse outcome.[99,100] These cases have been classified as "BCR-ABL–like" ALL on the basis of similarities in gene expression profiles with Ph chromosome–positive ALL.[99,100] Recent work has revealed that most of these "BCR-ABL–like" cases harboring Ikaros alterations, but lacking BCR-ABL translocations, commonly harbor mutational activation of tyrosine kinase signaling as a result of translocations or activating point mutations of receptor or cytoplasmic kinases, such as PDGFRB, CRLF2, EPOR, IL7R, FLT3, JAK2, and ABL1. Importantly, preclinical studies have demonstrated the potential therapeutic utility of targeting the aberrantly activated kinase involved for at least some of these cases.[101]

Hypodiploid ALL

The presence of hypodiploidy (<44 to 45 chromosomes) portends a poor prognosis in B-precursor cell ALL, with event-free survival (EFS) rates less than 40%.[102] Alterations in whole-chromosome number (aneuploidy) are very common in human cancer[103] and can be oncogenic.[104] However, the mechanisms through which hypodiploidy contributes to leukemogenesis in B-precursor cell ALL remain largely unknown.

A recent genomic study has shed key insights into the molecular pathogenesis of hypodiploid ALL.[105] Both copies of chromosome 21 were always retained in each of the 124 cases of hypodiploid ALL cases analyzed, which, given that trisomy 21 is one of the most common genetic alterations in B-precursor cell ALL, highlights the pathogenic role of additional copies of genes on chromosome 21 in B-precursor cell ALL.

Rather than representing a single subtype of ALL, hypodiploid ALL instead harbors distinct biologic subsets, including low hypodiploidy (32-39 chromosomes) and near haploidy (24-31 chromosomes), which differ strikingly on a molecular basis.

- *Near-haploid ALL (24 to 31 chromosomes):* Seventy percent of these cases are characterized by genetic lesions leading to activation of growth factor signaling pathways, including NRAS, KRAS, NF1, MAPK, FLT3, and PTPN11. Notably, deletions of tumor suppressors such as *NF1* and *PTPN11* were typically homozygous as a result of hypodiploidy, and loss of heterozygosity of tumor suppressors provides one mechanism through which hypodiploidy can contribute to oncogenesis. These data support the potential therapeutic utility of targeting these kinases, or their key downstream effectors, although such interventions await further preclinical investigation.
- *Low-hypodiploid ALL (32 to 39 chromosomes):* In marked contrast to near-haploid ALL, almost all cases of low-hypodiploid ALL harbored mutations of the *TP53* tumor suppressor, whereas mutations of growth factor signaling pathways were rare in this subset. Mutations of *TP53* were present in remission bone marrow specimens in almost half of pediatric cases, strongly suggesting a germline origin consistent with the Li-Fraumeni syndrome; indeed, germline transmission was confirmed in one kindred.[105] Given that the induction of aneuploidy triggers *TP53*-dependent cell cycle arrest,[106] these data support a model in which *TP53* inactivation occurs early in the pathogenesis of low-hypodiploid ALL, thus allowing the subsequent acquisition of hypodiploidy to be tolerated by these cells. However, it remains entirely unclear why *TP53* mutations should be so rare in other ALL subtypes with striking degrees of aneuploidy, including near-haploid and hyperdiploid ALL. Low-hypodiploid cases were also associated with a high frequency of inactivating mutations of the *RB1* tumor suppressor, as well as a very high frequency of mutations involving Ikaros family members, particularly *IKZF2* (encoding Helios), which was mutated in more than 50% of cases.

A subset of cases with an apparently hyperdiploid chromosome complement was found to in fact represent "masked" hypodiploidy in which the hypodiploid genome has undergone reduplication, based on loss of heterozygosity apparent on the single-nucleotide polymorphism arrays performed. Although these cases might be classified clinically as hyperdiploid ALL (which has a favorable prognosis), masked hypodiploid ALL cases are indistinguishable from the respective hypodiploid ALL subtype (low-hypodiploid or near-haploid) based on gene expression profiling and pattern of oncogenic lesions, thus suggesting the need for clinical tests to distinguish this subtype from cases of "typical" hyperdiploidy, which has a favorable prognosis. Given that chromosomes 4 and 17 are lost in almost all cases of hypodiploid ALL, the presence of these trisomies may help to distinguish cases of true hyperdiploidy from masked hypodiploidy.[107]

Early T-Cell Progenitor T-Cell ALL

Recent work has revealed that differentiation arrest at the earliest stages of T-cell development, defined either by absence of biallelic TCRγ deletion (ABD; indicating failure to complete V(D)J recombination) or by an early T-cell progenitor gene expression profile pattern, identifies an overlapping subset of T-cell ALL cases at very high risk for treatment failure.[29,30] These cases are associated with aberrant oncogenic signaling through the RAS-MAPK, PI3K-AKT, and JAK-STAT pathways, typically owing to associated mutations in *RAS*, *FLT3*, *IL7R*, *BRAF*, and *JAK* kinases, as well as deletions of the *PTEN* tumor suppressor.[30,86] These cases are defined as T-cell ALL based on expression of cytoplasmic CD3 and harbor mutations in defining T-cell ALL oncogenes such as *NOTCH1*.[29,30] However, these cases also harbor additional mutations that are typically seen in AML, myelodysplastic, and myeloproliferative syndromes, such as *RUNX1*, *ETV6*, *EED*, *EZH2*, *SUZ12*, *DNMT3A*, *IDH1*, and *IDH2*.[29,108,109] Moreover, gene expression analyses have shown that early T-precursor T-cell ALL harbors similarities to normal hematopoietic stem cells and AML leukemic stem cells. The identification of effective targeted therapies is a subject of active investigation.

CLINICAL MANIFESTATIONS

ALL may present insidiously or acutely, as an incidental finding on a routine blood cell count of an asymptomatic child, or as a life-threatening hemorrhage, infection, or episode of respiratory distress. Common presenting symptoms include fever, pallor, bruising, petechiae, bone pain (presumably secondary to stretching of the periosteum or joint capsule by leukemic infiltration), and limp.

Although ALL is primarily a disease of the bone marrow and peripheral blood, any organ or tissue may be infiltrated by the abnormal cells. Such infiltration may be clinically apparent by physical examination. At initial diagnosis, 30% to 50% of children have enlargement of the liver or spleen, with organs palpable more than 4 cm below the costal margins (see Table 50-1). Lymphadenopathy caused by leukemic infiltration is an equally frequent presenting sign. Generally, the degree of organ infiltration correlates with peripheral blood blast count, thus reflecting the total leukemic mass. Leukemic invasion of tissues may, however, be occult and detectable only by histologic sampling.

Peripheral Blood

Clinical laboratory data often provide a broad spectrum of abnormal findings at the time of diagnosis of leukemia. Anemia, abnormal leukocyte counts and differential, and thrombocytopenia are common (see Table 50-1). However, some children with ALL may have normal peripheral blood cell counts at the time of diagnosis, even when the bone marrow is replaced by leukemic cells.

The red blood cells are usually normochromic and normocytic. Failure of erythroid production is manifested by a low reticulocyte count. Peripheral blood smear may reveal teardrop forms and nucleated red cells, consistent with marrow invasion.

Platelet counts may vary from normal to extremely low. Most children have fewer than 100,000 cells/mm^3 at presentation, and the platelets are usually of normal size. In contrast to idiopathic thrombocytopenic purpura (ITP), thrombocytopenia at the time of ALL diagnosis is usually accompanied by other hematologic or physical manifestations of leukemia.[110]

There is a wide range of leukocyte counts observed at the time of diagnosis, from extremely low to more than 1 million cells/mm^3. Approximately 20% of children with ALL present with leukocyte counts of more than 50,000 cells/mm^3.[111] Even with high presenting leukocyte counts, absolute neutropenia is common. Blast forms may or may not be present on routine smears of peripheral blood. Even when present, peripheral blast cells may be misleading, and the definitive diagnosis of leukemia cannot be made from the morphologic examination of the peripheral blood. For example, myeloblasts may be detected in the peripheral blood when the marrow has been infiltrated by various disorders, including osteopetrosis, myelofibrosis, granulomatous infections, sarcoidosis, metastatic tumor, and even ALL. Additionally, in patients with leukemia, the morphologic appearance of leukemic blast cells in the peripheral blood may differ from that of the marrow. Peripheral blood flow cytometry may be useful in distinguishing malignant blasts from "normal" myeloblasts, and differentiating ALL from AML, in patients with high presenting leukocyte counts.

Hypereosinophilia has been described in association with ALL.[112] The eosinophilia may precede the diagnosis of ALL, appear at presentation, and then disappear with successful remission induction.[112,113] Eosinophilia in B-precursor cell ALL has been associated with the t(5;14)(q31;q32) translocation, involving the *IL3* gene on chromosome 5 and the IgH gene *(IGH)* on chromosome 14.[114,115]

In regard to hyperleukocytosis, approximately 10% of children with ALL present with extremely high leukocyte counts (>100,000 cells/mm^3) (Table 50-2).[2,3,116] In patients with markedly elevated leukocyte counts, blood flow in the microcirculation can be impeded by intravascular clumping of the poorly deformable blasts. This may result in local hypoxemia, endothelial damage, hemorrhage, and infarction, especially in the CNS and lung. Clinically significant leukostasis, resulting in intracerebral hemorrhage or respiratory failure, is more common with hyperleukocytosis in AML than in ALL.[117] In one series, neurologic or pulmonary symptoms or both were observed in 5% to 10% of children with ALL and a

TABLE 50-2 Presenting Features by Age in 5181 Children and Adolescents with Acute Lymphoblastic Leukemia (ALL) Treated on ALL-BFM Trials (1986-1999)

	Age (yr)		
Presenting Feature	<1 (2.5% of Patients)	1 to <10 (79% of Patients)	10-18 (18.5% of Patients)
Gender			
Male	52%	56%	61%
Female	48%	44%	39%
WBC count ≥100 × 10^9/L	59%	10%	15%
Phenotype

Modified from Moricke A, Zimmermann M, Reiter A, et al: Prognostic impact of age in children and adolescents with acute lymphoblastic leukemia: data from the trials ALL-BFM 86, 90, and 95. Klin Padiatr *217:310–320, 2005.*

CNS, Central nervous system; *WBC*, white blood cell.

*CNS-3, diagnostic cerebrospinal fluid specimen with five or more WBCs/high-power field and lymphoblasts seen on cytopsin preparation.

†Results for B-precursor cases only.

presenting leukocyte count higher than 200,000 cells/mm^3 and CNS hemorrhage was diagnosed in 2% of those patients (all of whom had leukocyte counts higher than 400×10^9/L).[117] Treatment of hyperleukocytosis consists of vigorous intravenous hydration. Red blood cell transfusions should be administered cautiously to avoid increasing whole blood viscosity and worsening symptoms. For patients with very high presenting leukocyte counts and symptomatic leukostasis, leukapheresis or exchange transfusion may prevent hyperviscosity and leukemia cell lysis–related problems.

Disseminated intravascular coagulation is infrequently observed in patients with ALL at diagnosis. It is more common in T-cell ALL as a result of thromboplastic substances released from T lymphoblasts.[118] It also has been reported in patients with the uncommon t(17;19) translocation, associated with the B-precursor cell immunophenotype.[119] Disseminated intravascular coagulation should be treated promptly with infusions of fresh-frozen plasma and cryoprecipitate.

Bone Marrow

Evaluation of the bone marrow by aspiration and biopsy is essential for making the diagnosis of leukemia. The marrow specimen is usually hypercellular and characterized by a homogeneous population of cells. In most cases of ALL, the marrow generally has more than 50% blasts.

A bone marrow aspirate may be difficult to obtain at the time of diagnosis. This is usually caused by the density of blast forms in the marrow, but it may be caused by marrow fibrosis or necrosis.[120,121] In such cases, a diagnosis can be made by bone marrow biopsy. "Touch preps" of the biopsy specimen can be helpful in elucidating morphology when aspiration is not successful.

Differences may occur in leukemic involvement found in marrow aspirates derived from widely separated sites. Patchy marrow involvement of leukemic infiltration has been reported at diagnosis and relapse.[122] If clinical findings suggest leukemia, but a single-site bone marrow specimen is nondiagnostic, the marrow should be sampled at additional sites.

The distinction between ALL with lymph node involvement and non-Hodgkin lymphoblastic lymphoma with bone marrow invasion (stage IV) is arbitrary. Commonly the disease is classified as ALL when there are more than 25% lymphoblasts in the marrow and as stage IV non-Hodgkin lymphoblastic lymphoma when there are fewer than 25% lymphoblasts in the marrow. Although the lymphoblasts of ALL and lymphoblastic lymphoma appear morphologically and immunophenotypically indistinguishable, gene expression profiling studies have suggested that there may be differences in underlying biology between these two diagnoses.[123] However, the distinction may not be clinically important because advanced-stage lymphoblastic lymphoma and ALL respond similarly to intensive ALL-type therapy.[124,125]

Extramedullary Leukemia

Although marrow replacement is the major cause of symptoms of leukemia, extramedulllary involvement may also contribute to presenting signs and symptoms.

CNS Manifestations

Up to 20% of children will have blast cells visible on a cytocentrifuged cerebrospinal fluid (CSF) specimen at diagnosis.[126,127] CSF lymphoblasts can usually be identified by the use of cytocentrifugation and Wright-Giemsa staining. Such morphologic evaluation is necessary to distinguish the pleocytosis of leukemic meningitis from that induced as a result of intrathecal chemotherapeutic agents (arachnoiditis) or from CNS infections.[128]

The vast majority of children with detectable CSF lymphoblasts at initial diagnosis do not have any symptoms related to CNS involvement. Symptomatic patients may present with diffuse or focal neurologic signs and symptoms, including manifestations of increased intracranial pressure (vomiting, headache, papilledema, and lethargy), seizures, and nuchal rigidity. Cranial nerve palsies can occur, with the facial nerve being the most frequently involved.[129,130]

Intracranial hemorrhage in patients with high presenting leukocyte counts is uncommon in ALL but can lead to severe and devastating neurologic consequences.[131] Clinically significant spinal cord involvement has been reported in ALL, manifesting as a localized epidural leukemic infiltrate compressing the cord.[132]

Anterior Mediastinal Mass

Leukemic infiltration of the thymus appears as an anterior mediastinal mass on a chest radiograph. It is observed in about 10% of newly diagnosed patients and is almost always associated with T-cell immunophenotype (see Table 50-1). Leukemic infiltration of the mediastinal structures may cause life-threatening tracheobronchial or cardiovascular compression. Pleural effusion may also be associated with thymic enlargement, which can exacerbate respiratory distress. Prompt initiation of systemic chemotherapy (e.g., corticosteroids) is necessary to handle such emergencies and, rarely, emergent radiation may be indicated.

Genitourinary Tract Manifestations

Testicular Enlargement. The clinical presentation of testicular ALL is a painless enlargement of one or both testes. Clinically detectable testicular leukemia is uncommon at diagnosis, occurring in 1% to 2% of boys, and does not appear to have prognostic significance.[133,134] Occult testicular involvement at diagnosis is more common, especially in the presence of a high tumor burden. In a study in which testicular biopsies were performed in boys with newly diagnosed ALL, approximately 20% had microscopic leukemic involvement.[135] However, this finding does not appear to have any prognostic significance, and routine testicular biopsies at the time of diagnosis to document occult disease are not recommended.

Other Genitourinary Tract Sites of Involvement. Ultrasonographically enlarged kidneys have been observed in children with ALL at the time of diagnosis and are believed to be primarily caused by leukemic infiltration.[136] Renal enlargement in acute leukemia also may be related to hyperuricemia, hemorrhage, and pyelonephritis. Hypertension is more commonly associated with the treatment of leukemia, especially with the prolonged use of corticosteroids, than with renal involvement. Occasionally, urolithiasis is observed at presentation or during therapy for ALL. Most renal stones in ALL patients are calcium-based in composition and occur most frequently during phases of therapy that include corticosteroids.[137]

Priapism is rare and usually associated with an elevated white blood cell count.[138] The pathogenesis may be caused by involvement of sacral nerve roots, or it may be related to mechanical obstruction of the corpora cavernosa and dorsal veins by leukemic infiltration or leukostasis.

Bone and Joint Manifestations

Bone pain, joint pain, and limp are common presenting symptoms in childhood ALL.[139-141] Bone pain may be the result of direct leukemic infiltration of the periosteum, periosteal elevation of underlying cortical disease, bone infarction, or expansion of the marrow cavity by the leukemic cells. Pain and swelling of the joint are less frequent but may be presenting manifestations of disease and can initially cause confusion in the diagnosis.[142] Migratory joint pain accompanied by swelling and tenderness can be misdiagnosed as juvenile rheumatoid arthritis (JRA) or rheumatic fever.[140,142]

Up to 25% of children with ALL have characteristic radiographic changes, such as osteopenia and fracture at diagnosis, including vertebral compression fractures.[140,141,143] Some patients have radiographic changes in the absence of bone pain, whereas others have bone pain unaccompanied by radiographic changes. Radiographic changes are most often seen in the long bones, especially around the areas of rapid growth (e.g., the knees, wrists, and ankles), and include subperiosteal new bone formation, transverse metaphyseal radiolucent bands, osteolytic lesions involving the medullary cavity and cortex, diffuse demineralization, and transverse metaphyseal lines of increased density (growth arrest lines).[144,145] The latter probably represent regions of growth arrest during active phases of the disease rather than direct infiltration by leukemic cells.

Gastrointestinal Manifestations

Hepatosplenomegaly is a common feature at the time of diagnosis. Severe hepatic dysfunction, manifested as hyperbilirubinemia, presumably from leukemic infiltration, has been observed at diagnosis in some children with ALL and can complicate initial therapy, because many induction agents are hepatically metabolized or hepatotoxic.[146,147] A short course of corticosteroid monotherapy before the initiation of multiagent induction chemotherapy may improve hyperbilirubinemia.[147]

Ocular Manifestations

Ophthalmic manifestations of leukemia can be observed in more than a third of all newly diagnosed patients.[148,149] Leukemia can involve almost all ocular structures. Retinal hemorrhages, the most frequent ocular abnormality, are presumably caused by thrombocytopenia or anemia.[150] However, local infiltration of the capillary vessel walls with subsequent rupture and hemorrhage also may occur, especially in patients with very high leukocyte counts. Ocular motor palsies and papilledema are indicative of meningeal leukemia. Occasionally the optic nerve may be directly involved by leukemic infiltration.[151] In such situations visual acuity may be markedly affected and patients may present with monocular blindness. Prompt radiation therapy may be necessary to salvage useful vision. Leukemic infiltration of the anterior chamber with hypopyon and iritis has also been reported and can be the first manifestation of relapse.[152] Symptoms include conjunctival injection, photophobia, pain, blurring, and decreased vision.

Pulmonary Manifestations

Pulmonary leukostasis, which can lead to respiratory failure, can be seen at diagnosis, especially in patients with high presenting leukocyte counts.[117] This complication is more common in AML than in ALL. Radiographic distinction among infection, leukemic infiltration, and hemorrhage may be difficult.

Dermatologic Manifestations

Skin infiltration is uncommon in childhood leukemia, with the exception of congenital leukemia (both AML and ALL).[153] Leukemia cutis typically manifests as red or violaceous papules, nodules, or plaques.

DIFFERENTIAL DIAGNOSIS AND PROGNOSIS

A careful history and physical examination, together with an examination of the peripheral blood and bone marrow, result in a straightforward diagnosis of leukemia in the vast majority of cases. However, at times, ALL may present as the signs and symptoms of other conditions. These include ITP, aplastic anemia, JRA, infectious mononucleosis and other infections, and metastatic solid tumors.

Differential Diagnosis

Idiopathic Thrombocytopenic Purpura

ITP is the most common cause of the acute onset of petechiae and purpura in children. Patients with ITP usually present with isolated thrombocytopenia, often with large platelets seen on a blood smear, contrasting sharply to the more generalized blood cell abnormalities and small platelets typically observed in patients with ALL.[110] Physical findings in ITP are usually limited to bruising or bleeding associated with thrombocytopenia. An occasional patient develops modest splenomegaly, probably caused by a recent viral infection. In most cases, the leukocyte level and differential count are unremarkable and there is no anemia unless bleeding has been substantial or an unrelated anemia is present. Bone marrow examination is rarely necessary in uncomplicated cases of pediatric ITP (i.e., children with otherwise normal blood cell counts, consistent peripheral blood smear, and absence of adenopathy, hepatosplenomegaly, or other concerning findings on physical examination). However, if the diagnosis of ITP is in question or any of these concerning findings are present, clinicians should consider marrow evaluation to rule out leukemia before starting corticosteroids to avoid partially treating occult ALL.[154] The bone marrow aspirate is usually diagnostic because the marrow elements in ITP appear normal or show increased megakaryocytes.

Aplastic Anemia, Myelodysplasia, and Myeloproliferative Disorders

Like patients with leukemia, those with aplastic anemia, myelodysplasia, and myeloproliferative disease may present with pancytopenia and have fevers or infections associated with granulocytopenia. Lymphadenopathy and hepatosplenomegaly are unusual in aplastic anemia. Also, the radiographic skeletal changes sometimes seen in leukemia do not occur in aplastic anemia. To differentiate acute leukemia from these other disorders, marrow biopsy is mandatory and usually revealing.

Rarely, patients with ALL present with a transient pancytopenia preceding the leukemic phase.[155] The pancytopenic period may persist for a few days or weeks and be accompanied by high fevers. Spontaneous recovery with a period of normal blood cell counts often occurs before the onset of ALL.[155] In those cases, ALL typically becomes manifest several months after the period of aplasia. However, ALL may also develop after a period of aplasia, without any recovery of blood cell counts.[156] Distinguishing pre-ALL pancytopenia from aplastic anemia may be difficult. Repeated bone marrow aspirates or biopsies ultimately establish the correct diagnosis by demonstrating areas of marrow that are infiltrated with lymphoblasts. The pathogenesis of the preleukemic pancytopenia prodrome is unclear; in one case report, leukemia-associated genetic lesions were identified in the aplastic marrow when it was retrospectively analyzed.[157]

Juvenile Rheumatoid Arthritis and Connective Tissue Disease

Because ALL often presents primarily as joint or extremity complaints (especially limp, arthritis, or arthralgia), it may be confused with JRA or other autoimmune disorders.[142] Children with JRA can manifest fever, pallor, splenomegaly, and anemia, and patients with ALL can present with a positive test for antinuclear antibody, highlighting how difficult it may be to distinguish these conditions from each other.[142] Because of this difficulty, bone marrow aspiration should be considered before initiating corticosteroid therapy in children with presumed JRA.

Infectious Mononucleosis and Other Viral Infections

Childhood infectious mononucleosis and other viral illnesses can masquerade as leukemia. Patients may have generalized lymphadenopathy, splenomegaly, rash, fevers, and peripheral blood lymphocytosis. The atypical lymphocytes observed with acute Epstein-Barr virus (EBV) and other viral infections can sometimes be confused with peripheral leukemic blasts because they are larger than normal lymphocytes. Usually, viral infections can be differentiated from leukemia without bone marrow aspiration, but the procedure is sometimes necessary for accurate diagnosis. The detection of acute EBV infection in the blood by serology or PCR testing may be helpful in establishing the correct diagnosis.

Metastatic Solid Tumors

ALL and neuroblastoma may have similar presenting signs and symptoms, including fever, bone pain, and pancytopenia. Children with neuroblastoma frequently have malignant involvement of liver, lymph nodes, bone, or bone marrow; the marrow involvement may be extensive. In the bone marrow, neuroblasts tend to cluster and form pseudorosettes, in contrast to the diffuse involvement generally observed in ALL. Other solid tumors also rarely present as extensive marrow involvement, including rhabdomyosarcoma and Ewing sarcoma, and can initially be confused with leukemia. If questions remain after the examination of marrow morphology, other studies, such as immunophenotype and cytogenetics, may be helpful in distinguishing leukemia from a metastatic solid tumor.

Prognostic Factors

An array of clinical and biologic features have been identified as prognostically significant in childhood ALL, including age, presenting leukocyte count, immunophenotype, chromosomal abnormalities (ploidy, translocations), the presence of overt CNS leukemia at diagnosis, and the rapidity with which patients respond to initial induction chemotherapy.[111] Ultimately the prognostic significance of any factor is treatment dependent and the importance of a particular presenting feature in predicting outcome may vary, depending on the therapy delivered to that patient.

Age

The age of patients with ALL significantly correlates with clinical outcome. In childhood ALL, infants and adolescents have a worse prognosis than patients in the intermediate age group (aged 1 to 10 years).[116] ALL in infancy (<1 year at diagnosis) is associated with high presenting leukocyte counts, increased frequency of CNS leukemia at presentation, and a high incidence of rearrangements of the *MLL* gene on chromosome 11q23 (see Table 50-2).[17,18,116] Even when treated with intensified regimens, infants with *MLL* gene rearrangements have a dismal prognosis, with long-term EFS rates ranging from 10% to 40%.[116,158-161]

Adolescents (10 to 21 years of age) with ALL also have a less favorable outcome than children aged 1 to 10 years, although it is not as poor as that in infants. Adolescents with ALL more frequently present with "high risk" features at diagnosis, including T-cell immunophenotype, higher presenting leukocyte counts, and a lower incidence of cytogenetic abnormalities associated with a favorable prognosis, including high hyperdiploidy and the *ETV6-RUNX1* gene fusion (see Table 50-2).[116,162] Multiple retrospective studies have shown that adolescents fare better with pediatric ALL regimens than on treatments designed for adults with ALL.[162,163-165]

Leukocyte Count

The initial peripheral blood leukocyte count is a significant predictor of treatment outcome, with worsening outcomes as the leukocyte count increases.[111] Since 1996, based on the recommendation of the Cancer Therapy Evaluation Program of the National Cancer Institute (NCI), many investigators have considered a leukocyte count of 50,000 cells/mm^3 as the level separating patients with a higher risk for relapse from those with a more favorable prognosis.[111]

Immunophenotype

Historically, immunophenotype was considered an important prognostic factor, with inferior outcomes observed in patients with mature B-cell and T-cell disease. However, if they are treated with more intensive regimens, children with T-cell phenotype fare as well as those with B-precursor cell disease.[25] As noted earlier, mature B-cell ALL is more effectively treated with the same therapy used for advanced-stage Burkitt lymphoma.[8,9]

Some investigators have reported prognostic differences within subsets of patients with B-precursor cell ALL. Initial studies have suggested that patients with pre–B-cell ALL (cIg+) have a worse outcome than those with early pre–B-cell ALL (cIg–).[166] Subsequent reports indicated that the adverse outcome of patients with pre–B-cell ALL was caused by the subset with the t(1;19) translocation.[167] However, with greater treatment intensity, even patients with this cytogenetic abnormality do not appear to have an adverse prognosis.[168]

An early T-precursor phenotype is observed in 10% to 15% of cases of childhood T-cell ALL. This subset was initially indentified by gene expression profile analyses and is characterized by a distinctive immunophenotype (CD1a and CD8 negativity, with weak expression of CD5 and coexpression of stem cell or myeloid markers).[29] Retrospective analyses suggested that patients with early T-precursor cell ALL have a poorer prognosis.[29,169] In another retrospective study, patients with T-cell ALL with early T-precursor cell features were identified by ABD, indicating failure to complete V(D)J recombination at this locus.[30] Like early T-precursor cell ALL patients defined by immunophenotype, T-cell ALL patients with ABD were also found to have an inferior prognosis.

In 15% to 30% of patients with newly diagnosed ALL, flow cytometry reveals coexpression of at least one myeloid antigen on the cell surface of the lymphoblasts.[32,33,36] Myeloid antigen coexpression has been associated with several genetic abnormalities, including the *ETV6-RUNX1* fusion [t(12;21)], *MLL* gene (11q23) rearrangements, and the Ph chromosome (*BCR-ABL* rearrangement), but is almost never observed in high hyperdiploid ALL (51 to 65 chromosomes).[33,35,170] Myeloid antigen coexpression was previously believed to be associated with an inferior outcome, but several more recent reports have indicated that it is not an independent prognostic factor.[33,171]

Chromosomal Abnormalities

Several recurrent chromosomal abnormalities are important prognostic factors in childhood ALL. Two abnormalities, high hyperdiploidy (51 to 65 chromosomes or a DNA index greater than or equal to 1.16) and the cryptic t(12;21) (*ETV6-RUNX1* fusion), have been associated with a favorable prognosis.[43] High hyperdiploidy is observed in 25% to 30% of cases of childhood ALL and is more common in younger (noninfant) children with B-precursor cell phenotype and low leukocyte counts. [172] The most favorable outcomes in high hyperdiploid ALL patients have been associated with the presence of trisomies of chromosomes 4, 10, and 17.[107,173,174]

The *ETV6-RUNX1* fusion, which is rarely detected by karyotypic analysis, has been identified in approximately 20% of children with ALL using other more sensitive techniques, such as fluorescence in situ hybridization and the reverse-transcriptase PCR assay.[175,176] Like high hyperdiploidy, the *ETV6-RUNX1* fusion is more common in younger (noninfant) patients with low leukocyte counts and is observed almost exclusively in patients with B-precursor cell phenotype.[42,176] Up to 80% of children with B-precursor cell ALL diagnosed between the ages of 2 and 7 years have either high hyperdiploidy or the *ETV6-RUNX1* fusion,[172] although almost never both; these two chromosomal abnormalities are almost always mutually exclusive.[172,177] Several studies have indicated that children with *ETV6-RUNX1*–positive ALL have favorable EFS rates.[42,43,176] When relapses are observed in children with *ETV6-RUNX1*–positive ALL, they tend to occur relatively late and may be more responsive to postrelapse salvage therapy.[176,178-180]

Chromosomal abnormalities associated with an adverse prognosis include hypodiploidy (fewer than 44 or 45 chromosomes),[102,181,182] rearrangements of the *MLL* gene on chromosome 11q23,[158,181,183] and the Ph chromosome [t(9;22)].[181,184-187] *MLL* gene rearrangements are more frequent in infants than in older children with ALL.[183] The incidence of Ph chromosome–positive ALL increases with age at diagnosis and is more common in adolescents and young adults.[184,186] Patients with Ph chromosome–positive ALL appear to fare better if treated with allogeneic hematopoietic stem cell transplantation (HSCT) in first remission[187]; recent work has suggested that favorable outcomes may also be achieved with the combination of tyrosine kinase inhibitors and intensive chemotherapy without transplant.[96,97]

Intrachromosomal amplification of the *AML1* gene on chromosome 21 (iAMP21), detected in 1% to 2% of children with ALL, may also be associated with an inferior outcome.[188] Patients with this abnormality appear to fare better with more intensified "high risk" treatment than with less intensive regimens intended for patients with "standard risk" disease.[189,190] The t(1;19) translocation, observed in approximately 5% of cases of childhood ALL, had been previously associated with inferior EFS rates, but more recently conducted clinical trials have not found that this translocation is associated with an adverse prognosis. Some investigators have reported that patients with the t(1;19) translocation are at higher risk for CNS relapses,[191] but this finding has not been confirmed by others.[43,192,193] Chromosomal abnormalities in childhood ALL are reviewed in depth in Chapter 44.

Overt CNS Disease at Diagnosis

Lymphoblasts in the CSF can be detected in 15% to 20% of children who present with ALL.[126,127] Some children, such as those diagnosed within the first 12 months of life and those with T-cell ALL, have a higher incidence of CNS leukemia at diagnosis.[116]

Most investigators consider the presence of overt CNS disease at diagnosis to be an adverse prognostic indicator, and these patients are usually treated with more aggressive therapy. CNS status at presentation is usually classified as CNS-1 (no blast cells), CNS-2 (fewer than five leukocytes/μL with blast cells), and CNS-3 (five or more leukocytes/μL with blast cells or cranial nerve palsy).[111] Historically, CNS leukemia was defined as CNS-3 status (observed in approximately 5% of patients at diagnosis).[126,127] CNS-3 status at diagnosis is associated with a lower probability of EFS.[127] Several investigators have reported that patients with CNS-2 status also have a higher risk for relapse, although it does not appear to be as high as in patients with CNS-3 status at diagnosis.[126,127] Intensification of CNS-directed therapy (e.g., increasing the frequency of intrathecal chemotherapeutic treatments) may abrogate the adverse prognostic significance of CNS-2 status.[194] Thus patients with CNS-2 status at diagnosis usually receive extra doses of intrathecal chemotherapy without other changes in treatment whereas those with CNS-3 status are typically classified as higher risk and receive more intensive systemic and CNS-directed therapies.

Traumatic lumbar punctures with lymphoblasts on cytospin have also been associated with an adverse prognosis.[127,195] Like patients with CNS-2 status, those with traumatic lumbar punctures with lymphoblasts at diagnosis may also benefit from additional doses of intrathecal chemotherapy.[127]

Early Response to Induction Chemotherapy

The rapidity with which a patient responds to initial chemotherapy is a significant predictor of long-term outcome. Early response to therapy has been evaluated using morphologic measures (residual microscopic leukemia) and more sensitive techniques, such as PCR assay and flow cytometry.

Morphologic Response to Therapy. Patients who require two or more cycles of induction chemotherapy to achieve complete remission have a much worse prognosis than those who achieve complete remission within 1 month of diagnosis.[196-198] The Berlin-Frankfurt-Munster (BFM) group treats patients with 1 week of corticosteroid monotherapy (and one dose of intrathecal methotrexate) before beginning multiagent induction chemotherapy and has reported that poor peripheral blood response at the end of that week (defined as an absolute blast count of 1000/mm^3) is an independent predictor of adverse outcome.[3] Others have reported that the rate of clearance of blasts from the peripheral blood after multiagent chemotherapy is also an independent predictor of relapse.[199-201] Similarly, the persistence of leukemia in bone marrow specimens obtained 7 or 14 days after beginning multiagent chemotherapy strongly correlates with poor outcome,[202] although intensification of therapy can abrogate the adverse prognostic significance of slow early response.[203]

Minimal Residual Disease. Minimal residual disease (MRD) evaluation involves the measurement of very low levels of leukemia using sensitive techniques, such as PCR assay or specialized multiparameter flow cytometry. Leukemic cells are identified using targets identified at diagnosis, including leukemia-specific immunophenotypes (for flow cytometry–based assays), chromosomal translocations, or lymphoblast-specific immunoglobulin or T-cell antigen receptor gene rearrangements (for PCR-based assays). Using these techniques, leukemia cells have been identified at levels as low as 1 in 1,000 to 1 in 100,000 cells.[204-207]

Many studies have demonstrated that MRD levels early in therapy are a significant and independent predictor of long-term outcome.[204,208-212] For patients achieving a morphologic remission at the end of induction therapy, those with higher levels of marrow MRD at that time point have a higher risk for relapse than those with lower or undetectable MRD.[204,208-210,212-214,215] The risk for relapse directly correlates with MRD level, that is, those with the highest MRD levels at the end of remission induction have the worst prognosis. High levels of MRD detected soon after beginning with postinduction therapy (weeks 12 to 14 of treatment) have also been associated with an increased risk for relapse,[215,216] as have high levels measured in the peripheral blood as early as day 8 and in the marrow at day 15 of induction therapy.[214,217]

Other Prognostic Factors

Gender and Race. Some investigators have reported that male patients fare worse than female patients.[218,219] This observation had been attributed, in part, to the risk for testicular relapse,[218] although higher relapse rates in males have been observed even when testicular relapse rates were low.[219] Race may also influence outcome, with lower EFS rates reported for African-American, Hispanic, and Native American patients, even after adjustment for differences in prognostically significant presenting features. [220-222] The reasons why patients of different race have varying responses to therapy on certain regimens have not been fully elucidated but may in part be related to differences in the biologic subtypes of ALL observed in different groups. For example, African-American children have a higher relative incidence of T-cell ALL and lower rates of high hyperdiploidy, a favorable genetic subtype of precursor B-cell ALL.[223] Hispanic children also have a lower frequency of *ETV6-RUNX1*–rearranged ALL[224] and, in one study, were noted to have a higher incidence of ALL with rearrangements of CRLF2, a subtype associated with an inferior prognosis.[225]

Pharmacogenomics. Several studies have suggested that outcome may be affected by how rapidly and effectively an individual patient metabolizes certain chemotherapeutic agents. Polymorphisms in genes involved in chemotherapy drug metabolism have been associated with risk for relapse.[226] More favorable long-term outcomes have been reported in patients with mutant thiopurine methyltransferase (TPMT) phenotypes involved in the metabolism of thioguanines, such as 6-mercaptopurine,[227,228] although such patients may also be at higher risk for developing significant treatment-related toxicities, including low blood cell counts, infection, liver dysfunction, and second malignancies.[229,230] Investigations of other genes, such as the glutathione S-transferase genes (encoding enzymes involved in the intracellular detoxification of various compounds)[231,232] and the folate metabolism genes (e.g., thymidylate synthase, methylenetetrahydrofolate reductase, and methylenetetrahydrofolate dehydrogenase)[233-235] have led to conflicting results, without clear consensus regarding the prognostic significance of various polymorphisms.

Treatment Adherence. Compliance with taking oral chemotherapy during the maintenance phase has been shown to impact outcome. In one study of pediatric ALL patients, nonadherence to 6-mercaptopurine (as assessed by electronic monitoring device that measured cap opening of the medication bottle) was associated with an inferior outcome. Adolescents and Hispanic patients were at higher risk for noncompliance. After adjusting for sex, NCI risk group, cytogenetics, ethnicity, and other factors, 6-mercaptopurine compliance was an independent prognostic factor, with a progressive increase in risk for relapse with decreasing levels of adherence.[236]

THERAPY

Historical Background

Over the past 50 years, there has been a dramatic improvement in the prognosis of children with ALL (Fig. 50-3). Prior to 1947, when the first complete remission in childhood ALL was attained by Farber and colleagues,[237] the median duration of survival from the time of diagnosis was 2 months.[238] During the 1950s, drugs such as 6-mercaptopurine, methotrexate, and corticosteroids were found to be active in leukemia-bearing mice and subsequently in human leukemias.[239,240] The first controlled clinical trials were conducted by Frei and associates,[241] who ushered in the era of single-agent (and soon thereafter combination-agent) antileukemic chemotherapy trials.[241,242] Active drugs introduced in the 1960s and 1970s included the anthracyclines (doxorubicin and daunorubicin), L-asparaginase, and the epipodophyllotoxins (etoposide and teniposide).[243-245]

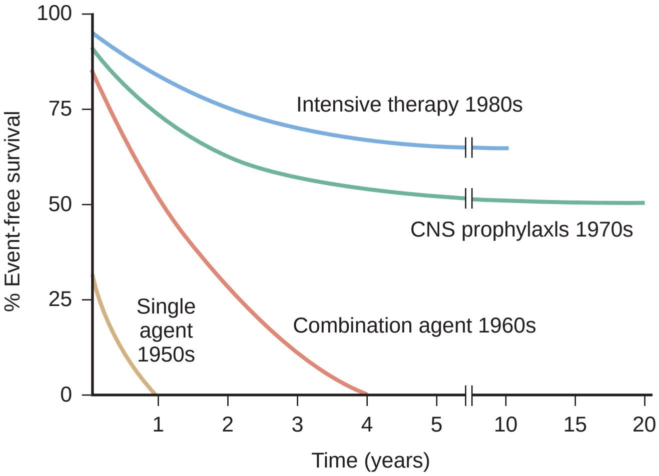

Figure 50-3 Historical perspective of the treatment of childhood acute lymphoblastic leukemia. The single-agent era resulted in few complete remissions and no cures. The combination-agent era without adequate central nervous system (CNS) treatment resulted in high complete remission rates but almost uniform mortality. Between the mid-1960s and 1970s, combination chemotherapy and CNS treatment resulted in prolonged, disease-free survival for approximately 50% of children. Intensive therapy in the 1980s and 1990s resulted in an event-free survival of 75% to 80% of children.

TABLE 50-3 Outcome by Presenting Features of 491 Children and Adolescents (Ages 0 to 18 Years) Treated on Dana-Farber Cancer Institute ALL Consortium Protocol 95-01 (1996-2000)

Presenting Feature	No. of Patients	10-Year EFS (±SE)	10-Year OS (±SE)

With current regimens for the treatment of childhood ALL, more than 95% of patients achieve complete remission and approximately 80% are long-term event-free survivors (Table 50-3 and Fig. 50-4).[24,246,247] Overall survival, which includes patients who are salvaged after relapse, is now approximately 90%.[248] Improvement in outcome over the past 30 to 40 years occurred despite the fact that, with few exceptions, the drugs used for the treatment of ALL today were all available by the late 1960s and early 1970s. Improvement in cure rates can be attributed to many factors, including the development of complex chemotherapeutic regimens designed to achieve clonal eradication, improvements in

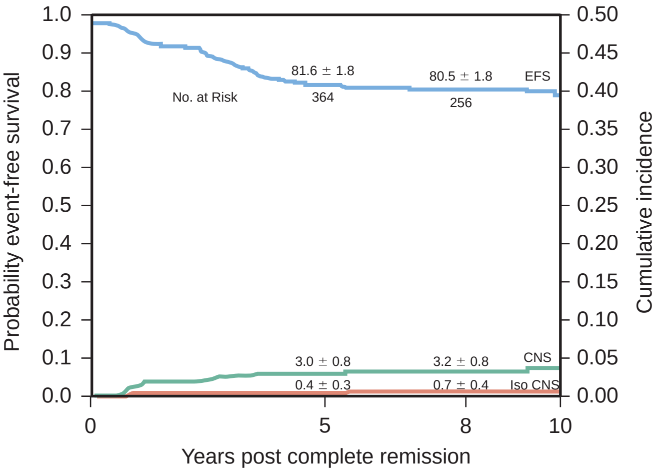

Figure 50-4 Event-free survival *(EFS)* and cumulative incidence of isolated or any central nervous system *(CNS)* relapse for 491 patients treated on Dana-Farber Cancer Institute ALL Consortium Protocol 95-01 (1996-2000). Median follow-up was 8.6 years. *(Modified from Silverman LB, Stevenson KE, O'Brien JE, et al: Long-term results of Dana-Farber Cancer Institute ALL Consortium protocols for children with newly diagnosed acute lymphoblastic leukemia [1985-2000].* Leukemia *24:320–334, 2010.)*

supportive care, recognition of the CNS as a sanctuary site, and application of risk-directed therapy.

Risk-Adapted Therapy

After the addition of CNS-directed therapy improved cure rates to approximately 50% in the 1970s, investigators compared presenting features in patients who were cured and those who relapsed to establish clinically relevant prognostic factors. Subsequent clinical trials used these prognostic factors to stratify therapy. More intensive therapy was administered to those patients considered to be at the highest risk for relapse. In contrast, some of the more morbid components of therapy were modified or eliminated for those children considered to have the best prognosis. The goal of risk-adapted therapy is to treat away adverse presenting features so that high-risk and low-risk patients have similar cure rates. For example, on Dana-Farber Cancer Institute (DFCI) ALL Consortium protocols, children with T-cell ALL (historically, a subgroup with an inferior prognosis) are treated as high-risk patients (receiving higher cumulative dosages of anthracycline and corticosteroid than lower-risk patients); with that therapy, their outcomes are as favorable as those with B-precursor cell disease.[25]

For many years, pediatric cooperative groups and institutions applied prognostic factors differently when defining risk categories for clinical trials. A more uniform approach to risk classification was proposed and agreed on at an NCI-sponsored workshop held in 1993.[111] For patients with B-precursor cell ALL, the standard-risk category was defined as age between 12 months and younger than 10 years and initial leukocyte count lower than 50,000/mm^3. The remaining patients were considered to have high-risk ALL. Other characteristics used by the various cooperative groups to classify patients as high risk include T-cell phenotype, CNS-3 status at diagnosis, and slow early response to initial therapy, including a high peripheral blood absolute blast count at the end of a 7-day prednisone prophase.[111] These various prognostic factors are discussed earlier.

Contemporary regimens have incorporated cytogenetic abnormalities and MRD levels into risk group stratification, and in some cases, only these factors are considered (and not more standard factors, such as age and leukocyte count) when assigning risk groups.[215] Patients with certain chromosomal abnormalities (e.g., *MLL* gene rearrangements and low hypodiploidy) are treated as high risk, regardless of other presenting features. Similarly, end-induction MRD is used by almost all groups as a factor determining the intensity of postinduction treatment, with patients found to have higher levels allocated to more intensive therapies.[215,249] On some protocols, MRD levels at a later time point (week 12) are also considered when risk-stratifying patients, because these have been shown to be prognostically important, especially in patients with T-cell ALL.[216]

MRD measurements, in conjunction with cytogenetics, have also been used to identify subsets of patients with an extremely low risk for relapse who may be successfully treated with less intensive therapies. The Children's Oncology Group reported a very favorable prognosis for patients with the B-precursor cell phenotype, NCI standard risk age/leukocyte count, CNS-1 status, and favorable cytogenetic abnormalities (either high hyperdiploidy with favorable trisomies or the *ETV6-RUNX1* fusion) who had low peripheral blood MRD levels at day 8 and low marrow MRD at end of induction.[214]

Ultimately, treatment is the most important prognostic factor, and those factors used to risk-stratify patients on one regimen may not be useful for patients treated on a different regimen.

Phases of Therapy

In general, treatment regimens for children with newly diagnosed ALL include three phases: remission induction, consolidation (or intensification), and continuation (or maintenance). The remission induction phase of therapy is designed to destroy measurable leukemia cells rapidly and minimize residual leukemia burden (i.e., the total number of leukemic cells in the body). The consolidation or intensification phase(s) is designed to reduce the total-body leukemia cell burden further and address issues of antileukemic drug resistance. The continuation or maintenance phase, consisting of low-dose chemotherapy, is designed to eradicate the residual leukemia cell burden. Throughout all phases, CNS-directed treatments (e.g., intrathecal chemotherapy) are an essential component because many systemically administered agents do not adequately penetrate the brain and spinal cord.

Remission Induction

After the diagnosis of ALL has been established and any urgent medical issues, such as metabolic imbalances, have been addressed, antileukemic chemotherapy should be initiated without delay. The initial phase of treatment, remission induction, is designed to reduce the leukemic cell burden to a clinically and hematologically undetectable level. *Hematologic remission* is defined as attainment of a normocellular bone marrow with 5% or fewer blasts and peripheral blood without lymphoblasts, with return of "normal" peripheral blood counts, that is, a granulocyte count exceeding 500 to 1000/mm^3 and a platelet count exceeding 100,000/mm^3. *Complete remission* is defined as achievement of these criteria along with the absence of any signs and symptoms of extramedullary leukemia. A complete remission must be induced before the next component of therapy is begun. The duration of most induction regimens is 4 to 6 weeks.

Clinical trials in the 1960s demonstrated that combinations of two agents were consistently superior to single agents for inducing complete remission in children with ALL. Vincristine and prednisone produced complete remission in approximately 90% of pediatric patients with ALL.[250,251] Addition of a third drug increased both the number of patients who achieved complete remission and the long-term relapse-free survival.[250,252] Current induction regimens, therefore, consist of at least three agents, most often L-asparaginase or an anthracycline, in addition to vincristine and prednisone.

Many groups have further intensified induction regimens to include four or more agents. In theory, these more intensive induction regimens may prevent the emergence of drug-resistant leukemic clones by an initial leukemic cell lysis of greater rapidity and magnitude.[253] The benefit in terms of long-term EFS of using four drugs during induction therapy (vincristine, prednisone, L-asparaginase, and an anthracycline) is widely accepted in higher-risk patients[254] but less clear in lower-risk patients.[255] Intensive induction regimens may enhance long-term EFS but can result in increased short-term morbidity, especially from infections during periods of granulocytopenia. However, even with four-drug induction regimens, few toxic deaths are reported (i.e., 1% to 2% of patients).[24,246,256]

The initiation of CNS treatment is an integral component of induction therapy. After the diagnosis of ALL has been established by bone marrow examination, a lumbar puncture is performed for diagnostic and therapeutic purposes. It is generally recommended that intrathecal chemotherapy be given with the first diagnostic lumbar puncture to reduce the theoretical risk for inadvertently seeding the meninges with peripheral blood lymphoblasts.[195] In addition to the diagnostic lumbar puncture, intrathecal chemotherapy is usually administered at least one more time during the first month of treatment. Patients with lymphoblasts present on their initial CSF specimen (CNS-2 or CNS-3 status, or traumatic lumbar puncture with blasts) typically receive more doses of intrathecal chemotherapy during the induction phase than those without any detectable CSF lymphoblasts (CNS-1 status).[127]

Failure to achieve remission after 1 month of therapy (induction failure) is uncommon, occurring in fewer than 5% of patients.[196,197] Induction failure is observed more commonly in patients with high presenting leukocyte counts or T-cell phenotype.[196,197] Successful treatment of refractory ALL has been reported with the use of drugs such as cytarabine, epipodophyllotoxins (e.g., etoposide, teniposide), and anthracyclines (e.g., idarubicin).[257-259] Nelarabine has been shown to induce remissions in patients with refractory T-cell ALL.[260,261] Ultimately, 80% to 90% of children with initially refractory disease are able to achieve a complete remission.[196,197] Despite this relatively high complete remission rate, overall survival for patients with a history of initial induction failure is poor (long-term overall survival rates of 20% to 30%).[196-198] Allogeneic HSCT in first remission may improve the outcome for patients with initial induction failure.[262] In a large retrospective series, a trend for superior outcome with allogeneic HSCT compared with chemotherapy alone was observed in patients with initial induction failure and either the T-cell phenotype (any age) or B-precursor cell phenotype and age younger than 6 years.[198] In that study, B-precursor cell ALL patients who were aged 1 to 5 years at diagnosis and did not have any adverse cytogenetic abnormalities (*MLL* translocation, *BCR-ABL*) had a relatively favorable prognosis, without any advantage in outcome with the utilization of HSCT compared with chemotherapy alone.

Consolidation (Intensification) Therapy

The goals of consolidation therapy are to reduce the disease burden further and to adjust the intensity of treatment based on the risk for subsequent relapse. A wide variety of agents and schedules have been used during postinduction consolidation in pediatric trials. In general, there has been an attempt in lower-risk patients to limit exposure to agents associated with significant acute and late toxicities while reserving the use of more intensive therapies for patients at higher risk for relapse.

A commonly used postinduction consolidation regimen was first introduced by the German BFM study group.[3] This consolidation scheme includes (1) a 4-week chemotherapy course (sometimes referred to as "consolidation" or "induction IB") immediately after the initial induction phase consisting of cyclophosphamide, low-dose cytarabine, and a thiopurine (mercaptopurine or thioguanine), followed by (2) an interim maintenance phase, which includes multiple doses of either high-dose or escalating doses of methotrexate with or without leucovorin rescue, and then (3) a reinduction course (or delayed intensification), which typically includes the same agents used during the initial induction/consolidation cycles. Augmentation of this regimen, including the use of two delayed intensification cycles instead of one, has led to improved outcomes for higher-risk patients, including those with a slow early morphologic response to initial induction therapy.[203,263-265] The DFCI ALL Consortium uses an alternative postinduction consolidation regimen that includes 20 to 30 weeks of L-asparaginase and, for higher-risk patients, additional doses of doxorubicin.[2]

Continuation Therapy

Almost all current treatment regimens for ALL include a phase of continuation or maintenance therapy, in which patients are treated with less-intensive chemotherapy to complete at least 2 years of therapy. Most continuation regimens consist of weekly low-dose methotrexate and daily oral 6-mercaptopurine. Some groups have added regular pulses of vincristine and corticosteroid to this regimen, although their benefit remains controversial.[266-268]

Several pharmacologic studies have documented highly variable bioavailability after oral administration of 6-mercaptopurine and methotrexate during the continuation phase.[269-273] This may have important prognostic implications, because lower intracellular levels of thioguanine nucleotides and methotrexate polyglutamates, the major metabolites of 6-mercaptopurine and methotrexate, have been correlated with a higher risk for relapse.[270,273,274] Variable bioavailability may be the result of various factors, including concurrent food, which may interfere with drug absorption.[272] Bioavailability of oral mercaptopurine appears to be improved if it is given in the evening, without food or milk.[272,275,276] Polymorphisms within genes involved in drug metabolism also affect rates of drug activation and clearance.[229] For example, patients with deficiency in the activity of TPMT, an enzyme that inactivates mercaptopurine, have higher rates of toxicity during continuation therapy (but also may have better survival) than patients with normal TPMT activity.[227,229] Most physicians attempt to compensate for the interindividual variations of bioavailability and metabolism by tailoring the dose of both drugs to the leukocyte count. Administration of maximally tolerated doses of methotrexate and 6-mercaptopurine during continuation therapy may improve outcome, as suggested by studies demonstrating that patients with lower leukocyte or neutrophil counts during continuation chemotherapy have lower relapse rates.[277,278] Lack of patient compliance with oral medications, as well as physician compliance with protocol dosages, may adversely affect the efficacy of continuation chemotherapy.[236,279,280]

6-Thioguanine is an alternative thiopurine that, unlike 6-mercaptopurine, does not rely on TPMT for its metabolism, resulting in higher intracellular levels of thioguanine nucleotides.[281] 6-Thioguanine also has been shown to be more potent than 6-mercaptopurine in inducing cell death of lymphoblasts in vitro.[282] The results of one randomized clinical trial comparing the two thioguanines indicated that 6-thioguanine was associated with a superior EFS (but not overall survival) in boys, primarily owing to a reduction in the frequency of CNS relapses.[283] However, other randomized trials comparing the two thiopurines did not confirm an EFS advantage for 6-thioguranine.[284,285] Additionally, the use of 6-thioguanine during the maintenance phase has been associated with significant hepatotoxicity, including veno-occlusive disease and cirrhosis, as well as higher remission death rates, primarily caused by infection.[283,284] Thus 6-mercaptopurine remains the thiopurine of choice during the continuation phase.

Several investigators have studied the relative efficacy and toxicity of two corticosteroids used during postinduction therapy: prednisone and dexamethasone. Interest in substituting dexamethasone for prednisone stems from studies suggesting that dexamethasone has more potent in vitro antileukemic activity, higher free plasma levels, and enhanced CSF penetration.[286-289] In several clinical trials conducted in the 1990s, the nonrandomized substitution of dexamethasone for prednisone appeared to affect outcome favorably.[290,291] This finding was confirmed in several randomized clinical trials that indicated that dexamethasone was associated with a superior 5-year EFS.[292-294] However, dexamethasone may also be associated with increased corticosteroid-related toxicities, including higher rates of fracture, osteonecrosis, and infectious complications, especially in older children and adolescents.[292-296] Thus the optimal corticosteroid preparation and dosing have yet to be determined and may differ based on presenting features (e.g., age) and risk for relapse.

Attempts to intensify continuation therapy by administering rotating pairs of non–cross-resistant drugs, including many agents not traditionally incorporated during the continuation phase, such as cyclophosphamide, epipodophyllotoxins, and cytarabine, have led to mixed results. In studies conducted by St. Jude Children's Research Hospital, this strategy resulted in improved outcomes for higher-risk but not lower-risk patients[297] but also was associated with high rates of toxicity, including secondary AML.[298] Based on this risk, these agents (especially epipodophyllotoxins) are, in general, no longer administered to most patients during the continuation phase.

CNS-Directed Therapies

In the 1960s, as systemic chemotherapy became more effective in prolonging the duration of hematologic remission in patients with ALL, the incidence of CNS leukemia as an initial site of relapse became progressively more common.[299,300] It was hypothesized that leukemia cells, even if subclinical, were present in the CNS in all patients and that these cells were protected by the blood-brain barrier from systemically administered chemotherapy. Thus, the concept of the CNS as a "pharmacologic sanctuary" (i.e., an anatomic space that is poorly penetrated by systemically administered chemotherapeutic agents) emerged. The introduction of radiation therapy to treat subclinical CNS leukemia in the 1970s was a pivotal step in boosting long-term disease-free survival rates in childhood ALL to 50%.[301] Although most pediatric patients are now treated without prophylactic cranial radiation, the importance of effectively treating subclinical CNS leukemia is undisputed for childhood ALL.

All successful treatment regimens for ALL include therapy directed at treating CNS leukemia. Options for CNS-directed therapies include cranial irradiation, intrathecal chemotherapy, and CNS penetrant systemic chemotherapy.

Radiation therapy was the first modality successfully used to prevent CNS relapses. The use of radiation for CNS treatment was based on experiments demonstrating that L1210 murine leukemia could be cured when cranial irradiation was added to systemic treatment with cyclophosphamide.[302] In the 1960s and 1970s, studies performed at St. Jude Children's Research Hospital documented the effectiveness of CNS radiation as preventive therapy in children with ALL.[303] In one study, patients were randomized to receive 2400 cGy of craniospinal radiation or no radiation. The difference in CNS relapse rates was striking: only 2 of 45 irradiated patients (4%) had their initial complete remissions ended by meningeal relapse, compared with 33 of 49 nonirradiated patients (67%).[304] Moreover, 31 of the patients who received prophylactic radiation remained alive after 18 to 20 years, compared with only 10 patients in the nonirradiated group. Subsequent studies demonstrated that 2400-cGy cranial irradiation with intrathecal methotrexate was as effective in preventing CNS relapse as 2400-cGy craniospinal irradiation without intrathecal chemotherapy.[305,306] Because craniospinal radiation was associated with increased toxicity, including excessive myelosuppression and spinal growth retardation, radiation directed only to the cranium administered with intrathecal chemotherapy became the standard form of CNS treatment in the 1970s.

Although 2400-cGy cranial irradiation (with intrathecal chemotherapy) effectively prevents CNS relapses in children with ALL, it is also associated with subsequent learning disabilities, growth and neuroendocrinologic abnormalities, and an increased risk for second malignant neoplasms. Thus many investigators have studied alternative CNS treatments, including lower doses of cranial radiation (1200 to 1800 cGy), systemically administered CNS-penetrant chemotherapy (i.e., agents known to achieve therapeutic levels in CSF), or intrathecal chemotherapy. Current regimens for childhood ALL include some or all of these CNS-directed therapies.

The proportion of patients receiving cranial radiation has decreased significantly over the past several decades; on current regimens, most pediatric patients are treated without radiation. When it is administered, cranial radiation is generally restricted to patients with a higher risk for relapse involving the CNS, especially those with T-cell disease, high presenting leukocyte counts, or CNS-3 status at diagnosis.[307] Doses lower than 2400 cGy have been shown to be effective, and therefore are typically used when cranial radiation is administered. For instance, CNS and marrow relapse rates were not significantly different when the dose of cranial radiation was lowered from 2400 to 1800 cGy in consecutive Children's Cancer Study Group trials.[308] The BFM and DFCI groups have successfully used 1200-cGy irradiation in the context of an intensive systemic regimen that included high-dose methotrexate (known to penetrate the CNS effectively).[294,309,310] Irradiated patients also typically receive intermittent intrathecal chemotherapy in addition to cranial irradiation as CNS preventive therapy.

Systemic therapy plays an important role in the prevention of CNS leukemia. Penetration of the CSF by drugs has been clearly demonstrated with the use of glucocorticoids[286] and high doses of methotrexate and cytarabine.[311,312] It has also been shown that systemically administered asparaginase, whose efficacy is a function of asparagine depletion, effectively lowers CSF asparagine levels.[313,314]

Intrathecal chemotherapy, used in conjunction with intensive systemic therapy and/or cranial irradiation, is an important component of CNS treatment. Many investigators have replaced cranial irradiation with frequent dosing of intrathecal chemotherapy, especially in lower-risk patients. The success of these efforts appears to depend on the frequency with which intrathecal chemotherapy is delivered, as well as the intensity and CNS penetration of the systemic chemotherapy administered. Investigators from the Children's Cancer Group demonstrated that administering intrathecal methotrexate throughout all phases of therapy was as effective in preventing CNS relapses in lower-risk patients as 1800-cGy cranial irradiation combined with only 6 months of intrathecal methotrexate, but only in the context of an intensified systemic regimen.[315] When a less-intensive systemic regimen was used, more CNS relapses were observed in nonirradiated patients. Similarly, in a DFCI ALL Consortium study, excessive CNS relapses were observed in standard-risk males when cranial irradiation was eliminated without increasing the frequency of intrathecal chemotherapy or the intensity of systemic chemotherapy.[316] However, in a subsequent study conducted by the same group, standard-risk patients who received more frequent doses of intrathecal chemotherapy had as low a CNS relapse rate as irradiated patients.[246] Some controversy exists regarding the relative efficacy of intrathecal methotrexate alone and "triple intrathecal chemotherapy" (intrathecal methotrexate, cytarabine, and hydrocortisone). In one randomized study in standard-risk patients, triple intrathecal chemotherapy was associated with a lower rate of isolated CNS relapse but there was no difference in overall EFS.[317] Randomized studies have also demonstrated that the use of dexamethasone instead of prednisone, which is believed to be less CNS penetrant, is associated with a lower rate of isolated CNS relapses in nonirradiated patients.[292,293] Thus those regimens that have successfully eliminated cranial radiation include extended and/or frequent dosing of intrathecal chemotherapy in conjunction with intensified, more CNS penetrant systemic therapy, including dexamethasone and/or high- or intermediate-dose methotrexate.[194,246,290,318-320]

Several clinical trials have been conducted on which cranial radiation was omitted for all patients, including high-risk subsets.[321-323] Most of these trials include multiple doses of either high-dose methotrexate or high-dose cytarabine and increased frequency of intrathecal chemotherapy. While the overall EFS on these trials was similar to that of contemporaneously conducted trials on which some patients received prophylactic radiation, some nonirradiated patient subsets had a significantly high risk for CNS relapse, including patients with T-cell phenotype or the presence of blasts in CSF at diagnosis. Additionally, some patients with high-risk features on these trials were treated with allogeneic SCT in first complete remission (which included total-body irradiation).[321]

The goal of eliminating cranial radiation in pediatric patients is to minimize long-term sequelae (see later). Although several studies have indicated that intrathecal chemotherapy and intensive systemic therapy can be as effective as cranial irradiation in preventing CNS relapses, the relative late neurocognitive toxicities of these CNS treatment strategies remains unsettled. Moreover, higher rates of acute neurotoxicity, including seizures, have been observed with regimens that included multiple courses of high-dose methotrexate and frequent doses of intrathecal chemotherapy.[324]

Cessation of Treatment

The optimal duration of therapy remains unknown. Most investigators continue to treat patients for 2 to 3 years, based on results of older studies, in which patients received therapy that was less intensive than in current regimens.[325] Randomized studies conducted by the Children's Cancer Group in the 1970s indicated that there was no significant difference in outcome when comparing 5 versus 3 years of therapy.[326,327] In the Childhood Leukaemia Trial UKALL VIII, a randomized study of 2 versus 3 years of continuation therapy conducted in the 1980s, the researchers observed no significant survival advantage with longer therapy. Patients receiving the shorter duration of therapy had a higher relapse rate, but this was counterbalanced by a higher remission death rate in those receiving 3 years of treatment.[328] Some early studies suggested that the optimal duration of therapy may be different for boys and girls, with boys benefiting from a more prolonged continuation phase,[329] although this finding may be less relevant with current regimens.

Even with more intensive regimens, attempts to shorten therapy duration from 2 years have not been successful. The BFM group randomized patients to receive 18 or 24 months of treatment and observed a higher relapse rate with patients who received the shorter course of treatment.[310] Similarly, high relapse rates were observed in a nonrandomized study conducted by the Tokyo Children's Cancer Study Group, in which patients received intensified therapy for only 12 months, suggesting that truncated therapy, even if intensive, is inadequate for most children with ALL.[330]

Treatment of Special Patient Subsets

Philadelphia Chromosome–Positive ALL Patients

The Ph chromosome, t(9;22)(q34;q11), which leads to fusion of the *BCR* and *ABL* genes, is detectable in approximately 5% of children and 20% of adults with ALL.[331] In pediatric ALL, it is more frequent in adolescents than in younger children.[116] When treated on regimens with conventional chemotherapeutic agents, these patients have a dismal prognosis, with long-term EFS rates ranging from 0% to 25%.[95,184-186] Allogeneic SCT in first remission has been shown to lead to more favorable outcomes and, prior to the availability of tyrosine kinase inhibitors, was considered the treatment of choice for children with Ph chromosome–positive ALL.[332] In one study, which reviewed the outcome of 610 children with Ph chromosome–positive ALL treated by 10 study groups in the pre–tyrosine kinase inhibitor era between 1995 and 2005, transplantation in first remission from an HLA-matched related or unrelated donor was associated with a higher likelihood of disease-free survival compared with chemotherapy alone.[187]

Imatinib mesylate is a selective inhibitor of the *BCR-ABL* tyrosine kinase. Phase I and II studies of single-agent imatinib in children and adults with relapsed or refractory Ph chromosome–positive ALL have demonstrated relatively high response rates, although these responses tended to be of short duration.[333,334] Results from pediatric trials have suggested that the administration of imatinib in combination with multiagent chemotherapy is feasible, without excessive toxicity.[96,97] In a pilot trial conducted by the Children's Oncology Group, patients treated with the combination of chemotherapy and imatinib (but without transplant) appeared to do at least as well as other patients on the same trial who underwent SCT in first remission.[96]

Infants

Patients diagnosed during the first year of life represent 2% to 4% of cases of childhood ALL.[335] The outcome of infants with ALL is significantly worse than that for older children, with reported long-term EFS rates of 20% to 40%.[160,336,337] The major cause of treatment failure is relapse, which tends to occur early, often in the first 1 to 2 years after diagnosis.[159,160,338-341] In vitro chemosensitivity assays have indicated that lymphoblasts from infants with ALL are relatively resistant to agents commonly used in childhood ALL regimens, such as corticosteroids and L-asparaginase.[342] Infants also appear to be more vulnerable to the toxic effects of therapy, especially severe infections.[160,339,343]

The poor outcome of infants appears to be related to the biologic distinctiveness of the disease observed in this age group. Up to 80% of infants with ALL present with molecularly detectable rearrangements of the *MLL* gene on chromosome 11q23.[17,18,160,161] The presence of a *MLL* gene rearrangement is an independent predictor of poor outcome in infant ALL, with the worst outcomes observed in *MLL*-rearranged patients who present at a very young age (<6 months at diagnosis) and with high presenting leukocyte counts.[160,161]

Because of their poor prognosis, infants with ALL are usually treated on separate protocols with intensified therapy. In vitro drug sensitivity testing and small, nonrandomized clinical trials have suggested that high-dose cytarabine, an agent more often used in AML, might benefit infants with ALL.[342-344] In the Interfant-99 trial, the largest clinical trial conducted for infants with ALL, a cytarabine-intensive regimen resulted in a 4-year EFS of 47%.[161]

The role of allogeneic SCT in first complete remission in infants with ALL remains controversial.[345,346] On the Interfant-99 trial, a subset analysis suggested that SCT in first remission may be beneficial in infants with high-risk features (*MLL* gene rearrangement, age younger than 6 months at diagnosis, and presenting leukocyte count at or above 300,000/µL); an EFS advantage for transplant was not demonstrated in other *MLL*-rearranged infants.[347]

Adolescents

Older children and adolescents (aged 10 to 18 years at diagnosis) have a less favorable outcome than children aged 1 to 10 years at diagnosis, and more aggressive treatments are generally administered to these patients. Adolescents present more frequently with adverse prognostic features, such as a high leukocyte count, T-cell immunophenotype, and the *BCR-ABL* translocation, and a lower frequency of favorable features, such as high hyperdiploidy and the *ETV6-RUNX1* fusion gene.[116,162,348] Adolescents also appear to be at higher risk than younger children for developing treatment-related complications, including osteonecrosis, pancreatitis, and thrombosis.[162,295,349] Several investigators have compared outcomes of older adolescents with ALL (aged 15 to 20 years) treated in pediatric or adult clinical trials, and all have found that these patients fare better with a pediatric regimen.[163-165,350] The superior outcome of older adolescents treated with pediatric ALL regimens may be related, in part, to the components of therapy; pediatric regimens tend to include higher cumulative dosages of vincristine, corticosteroid, and L-asparaginase than treatments designed for adults with ALL.[163]

Children with Down Syndrome

Children with Down syndrome have increased risk for developing both ALL and AML. Approximately one half to two thirds of cases of acute leukemia in children with Down syndrome are ALL. Although the vast majority of cases of AML in children with Down syndrome occur before the age of 4 years, ALL in children with Down syndrome has an age distribution similar to that of ALL in non–Down syndrome children.[351,352] Patients with ALL and Down syndrome almost always present with B-precursor cell phenotype and have a lower incidence of favorable and unfavorable cytogenetic abnormalities.[353-356] They appear to be at higher risk for developing treatment-related complications, especially those related to methotrexate, such as mucositis and myelosuppression.[357,358] Outcomes for children with Down syndrome and ALL have generally been reported to be less favorable than those of non–Down syndrome patients, which may be related to a higher incidence of treatment-related mortality because of infection and a lower frequency of favorable biologic features, such as high hyperdiploidy and the *ETV6-RUNX1* fusion.[352-356]

High expression of *CRLF2* occurs in 50% to 60% of cases of ALL in children with Down syndrome, compared with 5% to 10% of non–Down syndrome B-precursor cell ALL patients.[83,84,359] A higher frequency of activating mutations in *JAK2* has also been observed in Down syndrome ALL (~20% of cases)[360,361]; almost all patients with *JAK2* mutations also have *CRLF2* overexpression.[83,84,360] It does not appear that *CRLF2* genomic aberrations or *JAK2* mutations have independent prognostic relevance in Down syndrome ALL.[360] However, in one study, deletions of the *IKZF1* gene, observed in 35% of Down syndrome ALL cases (and frequently associated with *CRLF2* overexpression), was found to be a strong independent predictor of inferior EFS.[360]

COMPLICATIONS OF TREATMENT

At Diagnosis and during Treatment

At the time of diagnosis, the major clinical problems are the results of metabolic disturbances secondary to leukemia cell lysis, disrupted hematopoiesis leading to abnormal peripheral blood counts, and leukemic infiltration of nonhematopoietic organs. Initiation of chemotherapy may exacerbate these issues and lead to additional problems, including myelosuppression, bacterial and fungal infections, and mucosal toxicity.

Metabolic Complications

Rapid turnover of leukemia cells before and immediately after the initiation of chemotherapy leads to the release of intracellular contents, which can overwhelm the body's normal excretory mechanisms, especially in patients with high presenting leukocyte counts. The resultant metabolic disturbances include hyperkalemia, hyperuricemia, hyperphosphatemia, and hypocalcemia.[362,363] Patients with high levels of uric acid are at risk for the development of acute renal failure secondary to uric acid deposition in the kidney. To ensure that uric acid remains in solution in the renal tubule for optimal excretion, intravenous hydration should be instituted immediately after diagnosis to maintain dilute urine. In addition, administration of a xanthine oxidase inhibitor such as allopurinol, which prevents the formation of uric acid during cell lysis, should be started before the institution of antileukemic drugs. Recombinant urate oxidase, which catalyzes the breakdown of uric acid to the more soluble allantoin, may be used instead of allopurinol to decrease levels of uric acid rapidly, especially in patients presenting with high uric acid levels, high presenting leukocyte counts, or impaired renal function or in whom aggressive hydration is contraindicated.[364,365]

Hypercalcemia, although uncommon, has been reported in patients with ALL at diagnosis and appears to be related in many cases to elevated levels of parathyroid hormone–related peptide.[366] Hypercalcemia has also been associated with the t(17,19) translocation (*E2A-HLF* fusion), an uncommon chromosomal abnormality that also leads to disseminated intravascular coagulation.[366]

Infection

Life-threatening infection, observed at the time of diagnosis and during therapy, is one of the most frequent complications experienced by patients with ALL. Infections, most often bacterial and often associated with granulocytopenia, are the primary cause of treatment-related mortality in children receiving therapy for ALL.[256] Documented episodes of bacteremia have been reported in 15% to 30% of children receiving chemotherapy for ALL, and deaths caused by serious infection have been reported in up to 3% of patients.[3,256] Any febrile patient receiving therapy for ALL must be considered potentially bacteremic. Cultures should be obtained promptly, and the patient should be started immediately on broad-spectrum antibiotics with activity against bowel and respiratory organisms while awaiting culture results.[367]

As chemotherapy regimens have become more intensive, fungal disease, including invasive infections of *Candida* and *Aspergillus* species, have also been increasingly observed during the initial treatment of leukemia.[368,369] Viral infections can also cause significant morbidity in children with ALL. Varicella complicated by pneumonitis, hepatitis, or cerebritis can be particularly devastating.[370] Postexposure prophylaxis (within 72 hours) with varicella-zoster immunoglobulin and treatment with acyclovir once symptoms develop have reduced the frequency of severe disease.[371-373] However, even with these interventions, deaths from varicella have been reported in children undergoing therapy for ALL.[374] Rare cases of measles in children with ALL have been accompanied by a high incidence of morbidity and mortality.[375,376]

Pneumocystis jirovecii can cause a severe, often fatal interstitial pneumonitis in children receiving multiagent chemotherapy. The incidence of *P. jirovecii* increases with the degree and duration of immunosuppression and thus is usually observed during the later phases of ALL therapy, but it has been observed in the earlier phases as well.[377] Prophylaxis with trimethoprim-sulfamethoxazole markedly reduces the incidence of infection with *P. jirovecii* and is recommended for all children receiving therapy for ALL.[378]

The use of hematologic growth factors, such as filgrastim (granulocyte colony-stimulating factor), remains a matter of controversy. In prospective randomized studies, the use of filgrastim in children and adults receiving treatment for ALL was associated with a shorter duration of neutropenia and a tighter adherence to the planned treatment schedule.[379-382] However, although some investigators have reported a significantly decreased incidence in severe infections in patients treated with filgrastim during ALL therapy,[381,382] others have not confirmed this finding.[379,380] Also, filgrastim has not been shown to prolong survival or reduce the cost of supportive care for children with ALL.[380]

Typhlitis

A specific syndrome of right lower quadrant pain with rebound tenderness, abdominal distention, vomiting, and sepsis, referred to as typhlitis or necrotizing enterocolitis, can develop as a consequence of intensive chemotherapy, especially during the remission induction phase.[383,384] Findings on plain abdominal radiographs vary, but frequently show a paucity of air in the right lower quadrant.[383] Ultrasonography or computed tomography may reveal a characteristic thickening of the colonic mucosa.[384-386] The pathogenesis of typhlitis is most likely related to mucosal and bowel wall damage secondary to chemotherapy in the setting of prolonged neutropenia. It has rarely been observed before the institution of chemotherapy.[387,388] Management includes bowel rest, intravenous fluids, and broad-spectrum antibiotics. Surgery is usually not indicated, except in the rare case of perforation or uncontrolled bleeding.[389,390]

Acute Neurologic Toxicity

Intrathecal chemotherapy, high doses of systemic methotrexate, and cranial radiation, either alone or in combination, have been associated with acute neurotoxicity, including seizures.[324,391,392] Some of the highest rates of acute neurotoxicity have been observed in clinical trials that have used frequent dosing of intravenous and intrathecal methotrexate as a substitute for cranial radiation. For example, in a randomized trial conducted by the Pediatric Oncology Group in children with lower-risk B-precursor cell ALL, the incidence of acute neurotoxicity was approximately 10% in patients receiving repeated courses of intermediate-dose intravenous methotrexate compared with 4% in those receiving low-dose oral methotrexate.[324]

A transient episode of somnolence, anorexia, lethargy, and fever often can be observed 6 to 8 weeks after cranial radiation.[393,394] This “somnolence syndrome” often is accompanied by electroencephalographic changes, CSF pleocytosis, and fever.[395] Most children recover uneventfully, and it is unclear whether there are any long-term neurologic implications.[395]

Peripheral and autonomic neuropathy secondary to vincristine is frequently seen in children receiving ALL therapy. Signs and symptoms vary in severity and include constipation, absent deep tendon reflexes, distal muscle weakness, gait abnormalities, parasthesias, and cranial nerve palsy.[396] Rarely, postural hypotension, bladder atony, and the syndrome of inappropriate secretion of antidiuretic hormone can occur.[396,397] Vincristine-associated neurotoxicity is usually reversible after therapy is completed, and long-term sequelae are rare.[396,398]

Other Acute Toxicities

Therapy with L-asparaginase is associated with pancreatitis in 5% to 10% of patients, and allergic reaction occurs in up to one third of children.[246,291] L-Asparaginase can also induce coagulopathy by inhibition of protein synthesis of clot-forming and clot-inhibitory proteins, including antithrombin III, plasminogen, and fibrinogen.[399-403] CNS and peripheral thromboses have been observed in 2% to 4% of patients receiving L-asparaginase for ALL.[246,291,404] The use of this agent has also been associated with transient hyperlipidemia.[405] Complications from corticosteroids include hypertension, hyperglycemia, myopathy, mood and behavioral problems, and an increased incidence of bone fractures.[293,295,406-408]

Late Effects of Treatment

With prolonged survival of children with ALL, late effects related to the disease and its treatment have become increasingly evident. The clinical magnitude of late effects is a function of treatment and host-related factors, such as age at diagnosis. Late effects include neurocognitive deficits, short stature, obesity, bony morbidity, cardiac dysfunction, and second malignant neoplasms.

CNS Sequelae

Historically, low and low-average intelligence quotients were frequent findings in survivors of ALL.[409-411] These learning disabilities were related to a slow speed of processing information, distractibility, and difficulty in dealing with complex or conceptually demanding material.[412,413] With contemporary therapy, neurocognitive late effects appear to be less severe and are related to treatment and patient characteristics. For example, younger children (<3 to 5 years old at diagnosis) are more vulnerable than older children[409,411,414] and, in some studies, girls are more vulnerable than boys.[412,415-417] Children with meningeal relapse who receive a second course of CNS treatment are at particularly high risk for significant and progressive intellectual loss.[418-420]

Most long-term neuropsychological effects have been attributed to cranial radiation.[409,410,413,417,421] The most severely impaired long-term survivors are those who received cranial radiation doses (24 to 28 Gy) that are higher than doses used in current treatment regimens (12 to 18 Gy).[422-424] Long-term survivors treated with 18 Gy of radiation (especially those who were 3 years or older at diagnosis) appear to fare relatively well, with less severe neurocognitive sequelae than children who had received higher doses of radiation. In some studies, this group of survivors does not demonstrate any significant cognitive deficits, although subtle effects are observed with detailed neuropsychological testing.[414,425]

The contribution of systemic and intrathecal chemotherapy to the development of neurocognitive sequelae has not been fully elucidated. There is evidence that cognitive deficits are present in long-term survivors treated without cranial radiation,[424-427] but these deficits do not tend to be severe, and overall neurocognitive function is generally within the normal range.[417,428] In most studies of long-term survivors, nonirradiated patients have fewer and less severe impairments than those who received cranial radiation,[411,421] although with current chemotherapy regimens and lower doses of radiation, the differences between the two groups may be subtle.[425] Systemic chemotherapy, including high-dose methotrexate and dexamethasone, may also contribute to neurocognitive late effects.[424,429,430]

Neuropathologic changes in the CNS have been identified in survivors of childhood ALL. Leukoencephalopathy, a relatively rare phenomenon, is characterized by multifocal demyelination visible on radiographic imaging (computed tomography or magnetic resonance imaging).[431] Patients may present with a wide range of neurologic and behavioral problems, including poor school performance, confusion, memory problems, personality changes, and, in its most severe form, progressive dementia and coma.[431] Risk factors for the development of leukoencephalopathy include large doses of cranial radiation (2400 cGy or higher) or high cumulative doses of systemic and intrathecal methotrexate.[378] In one study, the development of leukoencephalopathy was associated with escalating doses of weekly systemic methotrexate beyond 50 mg/m^2 in previously irradiated children.[432] Microcephaly has also been reported as a late effect of CNS treatment and was found to be dependent on the radiation dose.[433] Radiation-induced cavernous hemangiomas and other vasculopathies, sometimes leading to cerebral hemorrhage, have been reported in survivors of childhood ALL.[434,435]

Growth

In several studies, survivors of ALL are shorter than expected for their age.[436-440] Although all survivors of childhood ALL appear to be at increased risk for adult short stature, the greatest impact on final height has been noted in patients treated with 2400-cGy cranial irradiation, with less severe growth failure noted in patients whose CNS treatment included 1800-cGy or no cranial irradiation.[437,440,441] Young age and female gender are associated with more severe growth impairment.[437,439,440] Short stature in survivors of childhood ALL is occasionally associated with growth hormone deficiency,[442-444] suggesting that growth hormone replacement may have a potential therapeutic role in some patients.

Obesity is also prevalent among survivors of childhood ALL and, like short stature, is more frequently observed in girls and in those treated at a young age.[439,445-448] The cause of obesity is unclear; some investigators have reported an increased risk for obesity in survivors who received cranial radiation, especially at higher doses (>20 Gy),[448,449] whereas others have not observed any relationship between body mass index and prior radiation.[439,447,450] Corticosteroids may also play a role in the development of obesity, with increased rates of obesity associated with higher cumulative dosages.[447]

Bony Morbidity

Bony morbidity, including osteopenia, fractures, and osteonecrosis, has been reported to occur in up to 30% of survivors of childhood ALL and is primarily secondary to corticosteroids.[295] Several investigators have demonstrated that children with ALL have reduced bone mineral density during therapy,[451,452] resulting in an increased risk for fractures during and immediately after treatment.[407,453] However, it appears that bone mineral density improves once therapy is completed, although some degree of residual osteopenia may persist.[454-457] The clinical implications, if any, related to persistent osteopenia in long-term survivors have not yet been fully elucidated.

Osteonecrosis, also known as avascular necrosis, is a disabling bony toxicity, frequently involving multiple joints. Osteonecrosis can lead to significant pain and loss of function, sometimes necessitating total joint replacement.[458-460] Symptomatic osteonecrosis has been observed in 2% to 9% of children treated for ALL, with higher rates associated with higher cumulative dosages of corticosteroids.[295,349,461] Osteonecrosis occurs much more frequently in adolescents than in younger children.[294,349,461-463] Female sex has also been identified as a risk factor for the development of this complication.[349,462,463] In some studies, dexamethasone (when used instead of prednisone) has been associated with a higher risk for osteonecrosis.[294,462]

Cardiac Sequelae

Echocardiographic abnormalities, particularly increased afterload and decreased contractility, are well-characterized late effects of anthracycline therapy.[464,465] The mechanism of this toxicity is impairment of myocardial growth. The severity of cardiac dysfunction is correlated with higher cumulative doses of anthracycline and higher dose rates.[464-467] Patients treated at a young age, females, and those with Down syndrome appear to be more vulnerable to anthracycline-associated cardiac toxicity.[466,467] Over the past two decades, as patients have received lower cumulative dosages of anthracyclines, symptomatic congestive heart failure has become increasingly uncommon and now only rarely occurs in long-term survivors of childhood ALL.[465,467] In a randomized study of children with high-risk ALL, the cardioprotectant agent dexrazoxane was shown to reduce the incidence of doxorubicin-associated myocardial injury (as measured by cardiac troponin-T during treatment and echocardiographic measures of ventricular wall thickness and function 5 years after therapy) without affecting relapse risk or EFS.[468,469]

Sexual Development and Fertility

Ovarian and testicular function are relatively unaffected by most current childhood ALL regimens,[438,470,471] with the possible exception of programs that use high cumulative dosages of alkylating agents (e.g., cyclophosphamide).[472,473] Prophylactic gonadal radiation can also impair subsequent ovarian or testicular function,[473] but this treatment is no longer included in most regimens. Thus sexual development is normal and fertility is preserved in the vast majority of survivors of childhood ALL.[474] In a study of 949 female childhood ALL survivors, almost all experienced menarche within the normal range, although prior cranial radiation increased the risk for both early and late menarche.[475] In both genders, normal pubertal growth spurts may be blunted.[438,470] No evidence currently indicates that the progeny of survivors of childhood ALL are at increased risk for congenital abnormalities.[476,477]

Cataracts

Survivors of childhood ALL appear to be at increased risk for the development of posterior subcapsular cataracts.[478-480] In general, these cataracts are small and do not impair vision. Cataract formation is believed to be related to the administration of corticosteroids during ALL treatment,[480] although the incidence of cataracts may be higher in ALL survivors who also received cranial radiation.[479]

Second Malignancies

Long-term survivors of childhood ALL are at increased risk for developing second malignant neoplasms, including AML, brain tumors, non-Hodgkin lymphomas, and carcinomas of the parotid and thyroid glands.[481-485] The overall cumulative incidence of second malignant neoplasms reported in the literature ranges from 1% to 6%, depending on the treatment regimen and length of follow-up.[481-484,486] Compared with age-adjusted expected incidence in the general population, survivors of ALL appear to have a 6- to 14-fold increased risk for developing another cancer.[481-484,486] Risk factors for the development of secondary AML include treatment with epipodophyllotoxins and alkylating agents.[487-489] For example, the cumulative risk for secondary AML was 5% to 6% after treatment with epipodophyllotoxin-containing regimens[487,488] but less than 1% after therapy lacking both epipodophyllotoxins and alkylators.[486,490] Cranial and craniospinal radiation have been associated with an increased risk for secondary solid tumors, primarily malignant gliomas and meningiomas.[481-484] In several large studies, the long-term cumulative incidence rates of secondary brain tumors in previously irradiated patients ranged from 1.0% to 1.6%.[481,486,491] It is unclear whether radiation dose is correlated with risk for secondary tumor, although, in one study, patients who had received 18 Gy of cranial radiation appeared to be at lower risk than those who had received 24 Gy of radiation.[482] The cumulative incidence of malignant glioma appears to plateau 15 to 20 years after diagnosis, although, even with 30 years of follow-up, a plateau in the incidence of meningiomas has not yet been observed.[483]

Other Sequelae

Abnormalities of dental and craniofacial development have been observed after cranial irradiation and appear to be related to the age of the patient at the initiation of therapy, with younger patients more severely affected.[492] Elevations of aminotransferase levels are common while patients are receiving therapy but are not associated with chronic liver disease once therapy is completed, and late-occurring hepatotoxicity is a rare phenomenon.[493,494] Chronic liver changes, including portal hypertension and cirrhosis, have been reported after the use of 6-thioguanine.[283,284,495]

RELAPSED ACUTE LYMPHOBLASTIC LEUKEMIA

Relapse subsequently ocurs in 15% to 20% of children with ALL who achieve remission after initial induction chemotherapy. Several factors have been identified that influence the outcome of patients with relapsed ALL, including duration of initial remission, site of relapse, and immunophenotype.

Duration of initial remission is one of the most important prognostic factors, with significantly worse outcomes observed in patients who relapse early—defined as those occurring while on or within 6 months from completion of initial therapy—than in those with longer initial remissions.[496,497,498] T-lineage immunophenotype and age older than 10 years at initial diagnosis have also been associated with an adverse prognosis after relapse.[496-498]

Site of relapse also has prognostic importance, with superior outcomes observed for patients experiencing isolated extramedullary relapses compared with marrow relapses.[497,498] Some studies have suggested that patients with combined marrow and extramedullary relapses have a better prognosis than those with isolated marrow relapses,[496,498] although this has not been consistently demonstrated.[497]

By using these prognostic factors, investigators have identified subsets of relapsed patients with a relatively favorable prognosis (e.g., patients experiencing a late extramedullary relapse) who may be able to maintain durable second remissions with conventional-dose chemotherapy. Patients with a less favorable prognosis, such as those experiencing an early marrow relapse, are considered candidates for more intensive therapies, such as allogeneic SCT.

Marrow Relapse

Relapses involving the marrow account for the majority of recurrences of childhood ALL. Induction of second complete remission can be expected in 70% to 90% of children with relapsed B-precursor cell ALL but is lower in children with T-cell immunophenotype and those whose relapses occur early (<36 months from initial diagnosis).[496,499-501] After a second complete remission has been attained, subsequent treatment may include conventional-dose or high-dose chemotherapy with SCT.

Chemotherapy

Most trials of conventional-dose chemotherapy have been unsuccessful at producing long-term survival in the majority of patients who experience a marrow relapse. In large published series, overall survival rates for children treated with chemotherapy alone (without allogeneic SCT) have ranged from 25% to 40%.[496,502,503]

Duration of initial remission significantly predicts the outcome of children with a marrow relapse who receive chemotherapy alone as salvage therapy. In almost all reported chemotherapy trials, overall survival after an early relapse is less than 20%.[496,503-505] The most successful chemotherapy trial results have been achieved with patients whose initial complete remissions exceeded 30 to 36 months. With intensive chemotherapy regimens, the probability of EFS for this subset of patients has ranged from 40% to 60%.[496,497,503,506]

MRD levels may also help identify patients with late marrow relapses who might respond favorably to chemotherapy-only regimens after a marrow relapse. Several groups have demonstrated that MRD levels measured at the end of the first month of reinduction therapy predict long-term outcome in patients who have experienced a marrow relapse and are treated with chemotherapy only, with significantly higher survival rates associated with lower levels of MRD.[507,508] Patients with a late marrow relapse with high MRD levels at the end of reinduction fare much less with a chemotherapy-only approach. In a study conducted by the BFM group, allogeneic SCT was associated with an improved outcome (compared with historic controls treated with chemotherapy only) in late relapsing patients with high MRD levels at the end of reinduction.[509]

Allogeneic Stem Cell Transplantation

Allogeneic SCT is an important treatment option for children with relapsed ALL.[510-514] In most published reports, the most common cause of failure after allogeneic SCT is recurrence of leukemia.[512-514] Survival after HLA-matched sibling SCT appears to be better when total-body irradiation is included in the preparatory regimen.[506,515] Therapy-related toxicity, including infections and severe graft-versus-host disease, is also a major cause of death, occurring in 15% to 30% of patients.[510-513,515,516] In recent years, the incidence of treatment-related complications appears to be decreasing with improvements in supportive care.[506]

As has been demonstrated in chemotherapy trials for relapsed ALL, duration of initial remission is an important predictor of outcome after matched-sibling SCT, with improved survival observed in patients with longer initial remissions.[506,510] MRD levels, measured at the end of reinduction therapy and just before transplantation, also have been shown to predict outcome after matched-sibling allogeneic SCT, with poorer survival rates observed for patients with higher levels of pretransplantation MRD.[517-519]

The indications for transplantation in second remission after marrow relapse remain controversial. Several studies have attempted to compare outcomes of patients treated with and without allogeneic SCT; however, there are many potential problems inherent in these analyses, including selection bias in terms of which patients receive a transplant. To address these issues, investigators have used matched-pair analyses and other statistical methods to control for time to transplantation and other important prognostic variables when comparing the two treatment modalities. In most of these reports, HLA-matched sibling SCT has been associated with a lower relapse risk and better survival rates compared with chemotherapy-only salvage regimens for patients with early marrow relapse.[506,510,511,514] However, these analyses have not clearly demonstrated that allogeneic SCT is associated with a survival advantage in patients with a late marrow relapse.[506,511] End-reinduction MRD may help to identify late-relapsing patients who might benefit from allogeneic SCT.[509]

HLA-matched siblings remain the donor of choice for allogeneic SCT for relapsed ALL. However, because over 80% of patients do not have histocompatible sibling donors, most patients needing allogeneic transplants rely on alternative donors. Other potential stem cell sources for transplantation include matched unrelated donors and umbilical cord stem cells. Historically, unrelated donor SCT in children with relapsed ALL was associated with a substantial risk for morbidity, with treatment-related mortality rates as high as 40% to 50% in some reports.[520,521] With improvements in supportive care and more accurate genomic typing of HLA antigens, treatment-related mortality after unrelated donor SCT has decreased significantly, making unrelated donor SCT a more viable treatment option.[522-524] Outcomes after unrelated donor SCT and unrelated cord blood SCT appear to be approaching those observed with HLA-matched sibling SCT.[524-526]

Autologous transplantation has also been investigated as an option for patients in second or subsequent complete remission who do not have a matched related donor. Autologous transplantation has been performed in conjunction with ex vivo purging of residual leukemia in harvested marrow via immunologic or pharmacologic techniques.[527-530] Relapse is the most common cause of treatment failure after autologous SCT, with a lower incidence of toxicity-related deaths than that observed after allogeneic SCT.[516] It does not appear that autologous SCT offers any advantage over chemotherapy[531] and, in general, should not be considered in pediatric patients with marrow relapses.

Isolated Extramedullary Relapses

Isolated extramedullary relapses, occurring either in the CNS or testis, are less frequent than marrow relapses in ALL. Such relapse may not actually be isolated; using sensitive molecular techniques, submicroscopic marrow disease can be demonstrated in most children at the time of an isolated extramedullary relapse.[532] The level of this submicroscopic marrow disease may predict response to postrelapse therapy.[532]

Isolated CNS relapse occurs in fewer than 10% of patients with ALL (see Fig. 50-4). Although CNS remission can be successfully induced in more than 90% of such patients with CNS-directed therapy, most patients treated without intensive systemic therapy will subsequently develop a bone marrow recurrence.[533,534] Thus, in addition to CNS-directed therapy, usually irradiation with intrathecal chemotherapy, patients with isolated CNS relapses are also treated with intensive systemic therapy. Several reports have indicated that intensive chemotherapy regimens in conjunction with cranial or craniospinal irradiation may provide adequate postremission therapy for patients with an isolated CNS relapse, with EFS rates as high as 70%.[535,536,537] From the limited published data, it is unclear that allogeneic SCT is associated with a survival advantage for patients with an isolated CNS relapse. In two published comparisons, outcomes after allogeneic SCT were similar to those achieved with chemotherapy and/or irradiation in children with an isolated CNS relapse.[538,539]

As with marrow relapses, patients experiencing late isolated CNS relapses have a better prognosis than those whose relapses occur earlier.[497,502,536,537] On two consecutive clinical trials conducted by the Pediatric Oncology Group, children with the B-precursor cell phenotype and a relatively late isolated CNS relapse (initial remission duration of at least 18 months) had EFS rates of 77% to 83% when treated with intensive chemotherapy and delayed cranial radiation, whereas patients with earlier relapses fared less well with the same regimen.[536,537] Some studies have indicated that patients whose initial CNS prophylaxis included cranial irradiation may have a worse prognosis after an isolated CNS relapse than previously unirradiated patients.[535]

Isolated testicular relapses are uncommon, occurring in 0.5% to 1% of boys with ALL.[24,246] For boys with isolated testicular relapses, systemic chemotherapy and testicular irradiation have resulted in prolonged second remissions in more than 80% of patients with late-occurring relapses.[540,541] This approach has been less successful in patients whose testicular relapses occurred during or soon after cessation of initial therapy, with long-term EFS ranging from 20% to 43%.[540,542]

Other rare sites of extramedullary relapse include eyes and ovaries. Case reports have indicated successful treatment of these patients with local irradiation and intensive systemic therapy.[543,544]

FUTURE DIRECTIONS

Although risk-adapted therapy has resulted in marked improvement in the outcome of children with ALL over the past few decades, molecular techniques may help identify biologic factors that may supplement or replace the currently applied clinical risk factors to identify those patients at highest risk for treatment failure. For example, using transcriptional profiling, single nucleotide polymorphism microarrays, transcriptional profiling, and other genomic assays, biologically distinctive and prognostically relevant subtypes of ALL have been identified, including the *BCR-ABL*–like and early T-cell precursors (ETP) subsets.[29,99,100] In addition, research focused on germline genetic variation and pharmacogenomics may identify patient-related factors that affect outcome and help lead to more individualized therapy.[226,545]

New drug development is essential to improve outcomes. Newer cytotoxic agents, such as clofarabine and nelarabine, may help improve the outcome of some high-risk patients but, like currently available drugs, are associated with significant side effects.[260,546] Imatinib and other tyrosine kinase inhibitors have dramatically altered the therapeutic approach to patients with Ph-chromosome–positive ALL[96] and are the prototypes of a new type of antileukemic agent that is more specific and potentially less toxic than current chemotherapy. Such agents target molecules or pathways that are important in leukemogenesis or leukemic cell survival, and, like imatinib, potentially could be given with cytotoxic chemotherapy to improve outcomes in high-risk subsets. For example, bortezomib, a proteasome inhibitor, was shown to be synergistic with other chemotherapeutic agents in vitro and so was tested in multiply relapsed patients in the context of a standard reinduction treatment platform, with promising preliminary results.[547] Other potential therapeutic targets under investigation include the mammalian target of rapamycin (mTOR), Janus kinase (JAK) family members in *CRLF2*-overexpressing B-cell ALL, and NOTCH pathway inhibitors in T-cell ALL.[548-550] Additionally, epigenetic modifiers, including proteins that regulate chromatin remodeling, DNA cytosine methylation, and covalent histone modifications, are increasingly recognized as potentially important therapeutic targets in leukemia.[551]

In addition to cytotoxic and targeted therapies, there is increasing focus on the role of immune-based therapies in ALL. Novel approaches that aim to promote autologous T-cell lysis of lymphoblasts include: (1) genetic engineering of autologous T cells to express a chimeric antigen receptor specific for a B-cell surface antigen and (2) use of a bispecific monoclonal antibody that both simultaneously engages T cells and targets B-cell surface antigens.[552,553] Toxin-conjugated monoclonal antibodies directed toward leukemia cell surface antigens are also under investigation.[554]

As more children with ALL become long-term survivors, there is an increasingly important need to address issues of late sequelae and the physical and emotional costs of cure.[555,556] While awaiting the development of more specific antileukemic therapeutic modalities, the impact of currently available primary and salvage therapies must be better understood so that rational therapeutic decisions can be made, with the ultimate goal of improving survival and minimizing toxicity.

In two consecutive studies (references 536 and 537), the Pediatric Oncology Group demonstrated that patients with late isolated CNS relapse had favorable outcomes when treated with regimens that included high-dose CNS–penetrant systemic chemotherapy and delayed cranial radiation.

553. Grupp SA, Kalos M, Barrett D, et al: Chimeric antigen receptor-modified T cells for acute lymphoid leukemia. *N Engl J Med* 368:1509–1518, 2013.

Chimeric angten receptor (CAR)-modified T cells represent a promising novel therapy for patients with relapsed, refractory ALL, as reflected in this report.

CHAPTER 51

Pediatric Myeloid Leukemia, Myelodysplasia, and Myeloproliferative Disease

Jason N. Berman and **A. Thomas Look**

CHAPTER OUTLINE

ACUTE MYELOGENOUS LEUKEMIA
- Epidemiology and Etiology
- Biology
- Molecular Genetics
- Morphology and Cytochemistry
- Immunophenotype
- Cytogenetics
- Clinical Presentation
- Treatment
- Prognosis
- Minimal Residual Disease
- Relapsed or Refractory Disease

ACUTE PROMYELOCYTIC LEUKEMIA
- Pathobiology
- Clinical Presentation and Risk Factors
- Treatment
- Central Nervous System Involvement
- Minimal Residual Disease Monitoring
- Relapsed Disease

DOWN SYNDROME WITH TRANSIENT MYELOPROLIFERATIVE DISORDER AND ACUTE MYELOGENOUS LEUKEMIA
- Down Syndrome with Transient Myeloproliferative Disorder
- Down Syndrome with Acute Myelogenous Leukemia

MYELODYSPLASTIC SYNDROMES
- Diagnosis and Classification
- Pathophysiology
- Inherited and Environmental Predisposing Factors
- Clinical Presentation
- Differential Diagnosis
- Treatment

MYELOPROLIFERATIVE DISORDERS
- Juvenile Myelomonocytic Leukemia
- Chronic Myelogenous Leukemia Caused by the *BCR-ABL* Fusion Gene
- Polycythemia Vera
- Essential Thrombocythemia
- Primary Myelofibrosis
- Mastocytosis

CONCLUSION

ACUTE MYELOGENOUS LEUKEMIA

Acute myelogenous leukemia (AML) comprises a heterogeneous group of disorders characterized by the malignant clonal transformation of a hematopoietic stem or progenitor cell. In recent years, deeper understanding has been gained into the chromosomal changes and specific genetic mutations that precipitate this transformation. AML is a relatively rare disorder in children, with between 500 and 600 newly diagnosed patients in the United States each year. Because of the heterogeneous nature of AML, it has proven difficult to find a treatment strategy that is effective for all patients; thus, overall cure rates for AML have improved only modestly in the past few decades, lagging behind those for acute lymphoblastic leukemia (ALL). Drawing from data from the Medical Research Council (MRC) trials, patients with AML are now risk stratified based on cytogenetic features and emerging data on the prognostic significance of minimal residual disease (MRD) early in therapy. Current ongoing clinical trials are attempting to minimize toxicity for patients with low-risk disease and intensify therapy for patients with high-risk disease. As the molecular genetics behind the biology of AML are better elucidated, there is a pressing need to develop new strategies for targeted therapy to improve outcomes in AML.

Epidemiology and Etiology

According to the National Cancer Institute (NCI) Surveillance Epidemiology and End Results (SEER) data, it was estimated that each year, from 2006 to 2010, 5.1 per 100,000 children younger than 14 years and 4.6 per

100,000 adolescents aged 15 to 19 years were diagnosed with cancer.[1,2] AML is less common than ALL: it comprises about 16% of childhood leukemias in children younger than 15 years but 36% of leukemias in adolescents 15 to 20 years, for a total of 500 to 600 new pediatric AML patients annually in the United States. AML has a bimodal distribution, occurring with higher incidence in children younger than 2 years and then again in adolescents 15 to 20 years old.

In ALL, boys are more commonly affected than girls; the incidence of AML is similar for all pediatric age groups, however, regardless of gender.[1,3] Similarly, although the incidence of childhood ALL is higher in white than in black children, the incidence of AML is comparable for both races across all pediatric age groups. With regard to ethnicity, there is a higher incidence of AML in Hispanic versus non-Hispanic children. Of interest, although the incidence of ALL for children younger than 15 years increased from 1977 to 1995, the incidence of AML did not change significantly over this time period.[3]

For a subset of patients with AML, a series of risk factors predisposing to the development of AML has been identified (Box 51-1) These risk factors fall into two general categories: exposures (environmental or toxic) and genetic predisposition. The best understood of the exposures is prior treatment with chemotherapy and radiation. Alkylating agents (e.g., nitrogen mustard, cyclophosphamide, ifosfamide, chlorambucil, and melphalan) are associated with the development of myelodysplastic syndrome (MDS) and secondary AML, with deletions of chromosomes 5 and 7.[4,5] Treatment with topoisomerase II inhibitors such as the epipodophyllotoxins has been linked to a specific type of AML with chromosome band 11q23 translocations, which produce fusion proteins involving the mixed-lineage leukemia (MLL) gene *(MLL)*.[6-10] Treatment with anthracyclines in adults with breast cancer, or in children for leukemias and sarcomas such as osteosarcoma, is associated with the development of secondary leukemias, including ALL, AML, and chronic myelogenous leukemia (CML).[11,12] Although therapy-related AML generally carries a worse prognosis than de novo AML, there have been reported cases of therapy-related AML harboring the better risk cytogenetic abnormalities: t(8;21), inv(16), t(16;16), and t(15;17), often in conjunction with other cytogenetic abnormalities.[13,14] In the case of therapy-related AML with inv(16) and t(16;16), a rare core-binding factor β *(CBFβ)*–myosin heavy chain 11 *(MYH11)* fusion transcript has been reported, with different breakpoints compared with the usual fusion transcript found in better-risk de novo AML.[14] Similarly, there is a case report of a patient with therapy-related AML with t(8;21), and the breakpoint at 21q22 was outside the *AML1* locus.[15]

Radiation exposure may be acquired from the environment or through medical procedures and is well documented to predispose to leukemia. The increased risk for AML and CML in survivors of nuclear blasts in Japan who were exposed to excessive doses of ionizing radiation has been well documented, and these patients have a higher rate of abnormalities of chromosomes 5 and 7.[16-18] An increased risk for AML and ALL in children exposed to radiation in utero has been described, particularly in the past, when diagnostic radiographs were more common during pregnancy,[19,20] although a retrospective study of children with leukemia in Sweden did not confirm this finding.[21] Nuclear power plant workers have a higher risk for leukemia, although there does not appear to be a higher risk in residents living near such plants.[22-24] Air travel is a source of exposure to cosmic radiation, and studies have shown an increase in malignant melanoma and other skin cancers in flight crew members, an increase in breast cancer in female flight crew members, and an increase in AML in male cockpit crew members who logged more than 5000 flight hours annually.[25,26] Studies designed to measure the potential risk for malignancy from residential or occupational exposure to magnetic fields around high-voltage electrical lines have generated conflicting results, and a causal relationship with AML has not been conclusively established.[27-35]

Box 51-1 Predisposing Factors for the Development of Acute Myelogenous Leukemia or Myelodysplastic Syndromes

PRENATAL EXPOSURES

Alcohol
Pesticides*
Foods naturally high in topoisomerase II inhibitors*
Viral infections

ENVIRONMENTAL EXPOSURES

Ionizing radiation
Chemotherapeutic agents
Alkylating agents
Epipodophyllotoxins
Anthracyclines
Organic solvents (e.g., benzene)
Radon*
Pesticides*
Viral infections*

HEREDITARY CONDITIONS

Down syndrome
Noonan syndrome
Neurofibromatosis
Fanconi anemia
Bloom syndrome
Severe congenital neutropenia (Kostmann syndrome)
Shwachman-Diamond syndrome
Klinefelter syndrome (XXY)*

GERMLINE PREDISPOSITION MUTATIONS

NF1 (for JMML)
RUNX1
CEBPA
GATA2
ANKRD26

ACQUIRED DISORDERS

Aplastic anemia
Paroxysmal nocturnal hemoglobinuria
JMML, Juvenile myelomonocytic leukemia.

*Conflicting or limited data.

There are several other environmental exposures with possible links to AML, some of which have yet to be proven definitively. Benzene exposure, which may occur occupationally or through tobacco smoking, has been shown to increase the risk for AML.[25,26,36,37] Several prenatal exposures have been studied as risk factors for the development of AML, particularly in children younger than 3 years. Maternal alcohol consumption during pregnancy was studied in a Children's Cancer Group (CCG) case-control study and found to have an association with increased rates of childhood AML in a dose-dependent matter, with an odds ratio of 2.64 overall and an odds ratio of 7.62 for classic French-American-British (FAB) classification category M1 (myeloblastic with minimal maturation) and M2 (myeloblastic with maturation) AML; other case-control studies have confirmed this finding.[38,39] Some early studies had suggested an association between maternal tobacco and marijuana use and childhood AML, but more recent analyses have not confirmed this association. A Children's Oncology Group (COG) case-control study looked at maternal consumption of foods such as soy, green and black tea, cocoa, red wine, and certain fruits and vegetables that are naturally high in DNA topoisomerase II inhibitors and found an odds ratio of 1.9 to 3.2 for the development of *MLL*-rearranged AML in the setting of high maternal consumption of these foods.[40] Some studies have suggested an increased risk for childhood AML after high exposure to pesticides, either prenatally or postnatally, up to 3 years of age.[41] There is interest in an association between viral infections and AML, but few data. One case-control study has suggested an increase in childhood AML in offspring of mothers who reactivated Epstein-Barr virus during pregnancy.[42] Parvovirus B19 is associated with pure red cell aplasia, and certain human leukocyte antigen (HLA)-DRB1 alleles seem to be associated with symptomatic infection.[43] One study of 16 leukemia patients suggested an association between parvovirus B19 infection and acute leukemia in 4 of the patients, including 1 patient with AML, all of whom carried these particular HLA-DRB1 alleles, although this association needs further investigation.[44] Several retrospective studies have suggested that breastfeeding may be protective against ALL and AML.[45-47] Risk related to indoor radon exposure is controversial. One French study showed a higher rate of AML in children with high exposure but other studies have showed no association.[48,49] Rarely used now, chloramphenicol use in children was formerly associated with an increased risk for AML.[50]

An increased incidence of AML has been observed for patients with certain hereditary disorders. Children with congenital disorders of myelopoiesis, such as Kostmann syndrome, Shwachman-Diamond syndrome, and Diamond-Blackfan anemia, are predisposed to AML.[51-58] Patients with inherited syndromes associated with chromosome fragility and impaired DNA repair mechanisms, such as Fanconi anemia[59-62] and Bloom syndrome,[63-65] also have an increased risk for development of AML. Neurofibromatosis type 1, which is caused by mutations in the neurofibromin tumor suppressor gene on chromosome 17, is associated with juvenile myelomonocytic leukemia (JMML).[66-68] Patients with certain constitutional chromosomal abnormalities carry a higher risk for AML.[69,70] Down syndrome is one of the most clinically prominent examples in this category. It is estimated that over 10% of infants with Down syndrome exhibit a transient myeloproliferative disease associated with a *GATA1* mutation.[71] Down syndrome patients have a 10 to 20 times higher than average risk for acute leukemia. In Down syndrome patients younger than 4 years, AML, usually acute megakaryoblastic (AMKL), is far more common than ALL: an estimated 1 in 500 Down syndrome patients develop AML.[71,72] In contrast to AMKL in the general pediatric population, which carries an extremely poor prognosis, this disease in Down syndrome patients is extremely sensitive to chemotherapy (see later).[71,72] Although early studies did not suggest a higher risk for AML in patients with Klinefelter syndrome (XXY), more recent data suggest that these patients may have a higher risk for hematologic malignancy, including AML.[73-75] More recently, a number of MDS/AML predisposition genes have been identified, including loss of function alterations affecting the key hematopoietic transcription factor genes *RUNX1, CEBPA*, and most recently *GATA2*.[76-80]

Although the predisposing risk factors and genetic conditions described may provide insight into the causative mechanisms that increase the risk for development of AML, most patients with de novo AML have no known predisposing exposures or conditions. Point mutations and chromosomal deletions and translocations occur at a background rate, even in healthy individuals, during hematopoietic stem and progenitor cell expansion. The extent to which inherited, expressed, single-nucleotide polymorphisms in the general population alter mutational rates during myelopoiesis and increase the risk for AML and other cancers remains an area of intense investigation.

Biology

Clonal Origin of Myeloid Leukemia Cells

Normal myelopoiesis is a complex differentiation program whereby primitive hematopoietic stem cells (HSCs) develop along a multistep pathway into fully differentiated, functionally active circulating blood cells.[81] This exquisitely controlled process is regulated by the intricate interactions among the expression levels of various transcription factors, growth factors and their receptors, cytokines, enzymes, and still unidentified novel molecules. A series of sequential genetic abnormalities perturbs this normal developmental progression and leads to AML. Although the relationships between specific morphologic subtypes of AML and their specific recurring genetic abnormalities have provided some insight into the mechanisms of leukemogenesis, understanding of the process whereby these fusion gene products interact with normal signal transduction pathways to subvert hematopoietic cell development is incomplete.[82]

Several strong lines of evidence support the hypothesis that AML progresses from a single transformed hematopoietic stem or progenitor cell. More than 30 years ago, studies were pioneered by Beutler and colleagues[83] and Fialkow[84] using X inactivation patterns in female patients to establish the clonal origin of human malignancies, including leukemia. By showing the presence of a single glucose-6-phosphate dehydrogenase (G6PD) isoenzyme in the leukemic myeloblasts of heterozygous females, the clonal origin of myeloid leukemia cells was demonstrated.[85-87] Females who are heterozygous at the G6PD locus express two isoforms of the enzyme. Approximately half of the cells in normal somatic tissue have randomly inactivated one of the X chromosomes, and approximately half of the cells should therefore express each isoform. Unlike normal somatic cells, AML cells of female patients heterozygous for G6PD expressed only one G6PD isoform, indicating cells of clonal origin.[86,87] In the 1980s, Vogelstein and coworkers[88,89] developed a strategy using X chromosome–linked DNA restriction length fragment polymorphisms to determine the clonal origin of human tumors. They established that maturing granulocytic cells arise from the malignant clone in patients with AML.[90] Later, X chromosome inactivation to determine clonality in malignancies was carried out using the polymerase chain reaction (PCR) assay to distinguish X-linked polymorphic genes.[91-93]

Transformation of Stem Cells with Self-Renewal Capacity

These earlier studies, and those performed by Bonnet and Dick and associates in the 1990s,[94,95] led to the insight that leukemia cell populations form a hierarchy in which leukemia stem cells or leukemia-initiating cells (LICs) are responsible for their own self-renewal and for the generation of the more differentiated progeny within the leukemic clone. This theory was in contrast to the stochastic model, which stated that malignant properties within cancer cell populations follow Gaussian distributions, resulting in the random or stochastic probability that individual cancer cells within the population are able to initiate malignant progression. Whereas AML was the first human cancer in which cancer stem cells were identified, the case has now been made in breast cancer,[96] brain tumors,[97-99] and colon cancer,[100] among others. In general, AML stem cells are believed to arise through the transformation of HSCs, which then retain the capacity for self-renewal, or through transformation of more differentiated hematopoietic progenitor cells that acquire the ability to self-renew by virtue of the particular transforming mutations, such as the formation of an *MLL* fusion gene.

AML is a heterogeneous disease in its clinical manifestations, response to therapy, and molecular genetics; thus insight into the cell of origin would have important ramifications regarding diagnosis and treatment. Moreover, refractory disease and relapse are often attributed to the presence of an LIC population that is resistant to chemotherapy; thus the ability to identify and target this subpopulation may be key to improving overall disease outcome.[101] In the 1990s, Dick's group produced a series of convincing papers[94,95,102] that strongly implicated the primitive, pluripotent HSC as the LIC in some types of AML. "Stemness," or the capacity to function as an LIC, includes self-renewal, proliferation, and differentiation and is tested in vitro by replating limiting dilution studies and in vivo by serial transplantation assays with the ability to regenerate a clonal leukemia in secondary and subsequent recipient animals. The HSC, with its inherent gene programs ensuring self-renewal, proliferation, and survival appears to be an ideal target to become sabotaged through a series of genetic events, leading ultimately to a fully transformed AML LIC that is capable of producing a clonal population of leukemia cells. According to this argument, different AML phenotypes often occur as a result of the gene(s) that are altered, leading to differentiation arrest within the progeny of the LIC, but not necessarily reflecting the degree of the commitment of the initially transformed cell. Support for this hypothesis initially came from several clonality studies in leukemic cells from patients with AML,[103-105] which demonstrated multiple-lineage involvement in a high proportion of cases, and implicated a multipotent HSC as the cell of origin.[104] More supportive evidence has come from studies looking at cytogenetic markers and characteristic cell surface antigen expression patterns.[106] Pluripotent HSCs express CD34 but do not express CD38 or HLA-DR, whereas more committed myeloid progenitor cells are CD34+, CD38+, and HLA-DR+.[81,106] Using fluorescence-activated cell sorting (FACS) of leukemic cell populations, the same two subpopulations, CD34+/CD38– and CD34+/CD38+, were isolated from the bone marrow of patients with different AML subtypes. The two subpopulations were then evaluated using fluorescence in situ hybridization (FISH) to determine the presence of cytogenetic abnormalities. The studies detected the same characteristic cytogenetic abnormalities in the CD34+/CD38– stem cell fraction as in the original leukemic bone marrow samples, implying origin in a very early HSC compartment.[107,108]

Further evidence supporting the stem cell origin model of AML was derived from transplantation experiments in which purified human AML cells were transplanted into mice with severe combined immunodeficiency (SCID). These experiments defined a SCID mouse leukemia–initiating cell (SL-IC) in the bone marrow of patients with AML and showed that these SL-ICs are CD34+/CD38– and that their engraftment produces large numbers of colony-forming progenitors. The CD34+/CD38+ and CD34– fractions did not engraft.[95] Similar results were obtained through transplantation studies in a modified SCID mouse, the nonobese diabetic mouse with SCID (NOD/SCID), with cells from patients with AML.[94] These studies identified and analyzed AML stem cells from samples of different FAB subtypes on the basis of their ability to initiate human AML after transplantation in NOD/SCID mice. These SL-ICs were able to proliferate and differentiate after transplantation, producing disease in the mice identical to that in the donor, as well as being able to renew themselves, reestablishing AML in secondary recipients, demonstrating that SL-ICs are capable of self-renewal. Again, the SL-ICs were found to reside in the CD34+/CD38– fraction and not in the CD34+/CD38+ or CD34– fractions. The SL-IC phenotype was consistent regardless of the FAB subtype (e.g., M1, M2, M4, M5). As few as $2 \cdot 10^4$ CD34+ cells were able to initiate the leukemic clone in recipient mice, whereas 100 times as many CD34– cells failed to engraft. Cells with the CD34 surface antigen were further fractionated on the basis of

CD38 expression. Only the CD34+/CD38− fraction contained SL-ICs.[94]

Whereas the transformation of the HSC provides an attractive mechanism to generate hierarchical myeloid leukemia cell populations, several studies have given new credence to a second mechanism through which committed progenitor cells along the pathway of myeloid differentiation are vulnerable to transforming mutations that confer self-renewal properties to progenitor cells that inherently lack this ability.[109-111] These transformation events create an LIC capable of generating a population of aberrant cells blocked at the differentiation state at which the initial transforming event occurred. Several translocations involving the *MLL* gene have been shown to initiate self-renewal in myeloid progenitor cells and to result in an AML phenotype.[110,112] A head-to-head comparison was conducted by retrovirally transducing the human AML-associated *MLL-ENL* fusion gene into murine HSC, common myeloid progenitors (CMPs), and granulocytic-monocytic–restricted progenitors (GMPs) and evaluating the relative transforming ability and resultant phenotype in each cell type. AML developed in mice transplanted with any of the three transduced cell populations and, in each case, displayed an identical myelomonocytic phenotype as assessed by morphology and flow cytometry.[110] Similarly, the *MOZ-TIF2* fusion gene was able to confer self-renewal properties to committed myeloid progenitor cells and resulted in AML when transplanted into irradiated mice.[111] Although the fusion genes *MLL-ENL* and *MOZ-TIF2* appear to impart leukemogenic capabilities to committed progenitor cells convincingly, other fusion genes such as *BCR-ABL* can induce leukemic transformation only when expressed in an HSC but not a more mature myeloid cell. Similarly, the potent oncogenic combination of *Hoxa9* and *Meis1* only resulted in AML when transduced into HSCs but not in more committed myeloid progenitors. In this case, expression of β-catenin was found to be the necessary factor for oncogenesis. Present in HSCs but absent in more committed progenitors, the addition of β-catenin to progenitors transduced with *Hoxa9* and *Meis1* was sufficient to lead to AML.[113] These findings point to the differing transforming abilities of different oncogenes that are likely cell-type and cell-context specific.[114] Hence both cell-of-origin hypotheses appear to be correct, depending on the specific oncogene or tumor suppressor that provides the initiating genetic lesion. Increased proliferation, survival, and self-renewal are all necessary attributes of a leukemia stem cell. Some genetic abnormalities, such as *MLL-ENL* and *MOZ-TIF2*, may be capable of inducing self-renewal and thus are able to transform a more differentiated myeloid cell into an LIC. By contrast, other oncogene fusions, such as *BCR-ABL*, or oncogenic transcription factor genes, such as *Hoxa9*, do not possess self-renewal capabilities and thus require a cell that inherently has this characteristic, namely, the HSC.

More recently, challenges to the cancer stem cell hypothesis have arisen out of a number of studies, predominantly in solid tumors such as melanoma, where the frequency of cells capable of giving rise to a new tumor in an immunocompromised host is of sufficient frequency to call into question whether the LIC represents a unique subpopulation or the original stochastic model of cancer progression holds true.[115] These studies have again called into question previously accepted tenets. CD34+/CD38+ populations, in addition to the CD34+/CD38−, have also been found to contain LICs when injected into more immune-deficient hosts that lack key components of the innate immune system.[116] These studies and additional syngeneic and cogenic transplant studies in mice as well as zebrafish[117-120] highlight the critical context of the recipient animal in determining the LIC. The heterogeneity of LICs in AML is further demonstrated by an increasing number of cell surface markers in addition to CD34 and CD38, including CD123, TIM3, and CD47.[121-123] Additionally, a number of studies have attempted to identify a specific LIC genetic signature, which has been found at least in some cases to independently predict prognosis. In this case, the LIC signature was reminiscent of the normal HSC, hearkening back to the original predictions of Dick's group highlighting the HSC as a putative LIC cell of origin.[124] However, although these findings are provocative, a consistent cadre of LIC genes has not yet been established. Clonality studies demonstrating the progressive acquisition of mutations in a given cell have also been put forward as an alternative to the cancer stem cell hypothesis.[125,126] Although seemingly at odds, these different concepts can be reconciled into a single integrated framework. Myeloid (and lymphoid) leukemia-initiating events may occur in both HSCs and committed progenitor cells, and each leukemia arises from a combination of multiple genetic abnormalities.[127] Secondary events subsequently are acquired in different subpopulations, generating unique clones with varying malignant potential depending on the genetic lesion and the self-renewal capacity of the cell in which these abnormalities occur. The number of genetic lesions necessary to cause frank AML is being defined based on next-generation sequencing studies recently published by the group at Washington University in St. Louis as well as other centers. The evolution of particular clones appears to determine the eventual phenotype of the AML cells documented at diagnosis (Fig. 51-1).[128,129]

These new discoveries have added additional complexity to our understanding of the contribution of LICs to AML pathogenesis by demonstrating that the heterogeneity inherent in this disease extends to the AML stem cells.[130] However, the identification of new LIC surface markers, genetic signatures, and gene-specific mutations hold out promise that LIC-targeted therapies will be realized in the coming years.

Molecular Genetics

Recent AML protocols have incorporated current knowledge regarding the significance of specific genetic abnormalities to direct risk-stratified approaches to treatment. Chromosomal abnormalities and, in particular, translocations identified on cytogenetic examination of the blast cells represent the initial genetic lesions incorporated into disease taxonomy and formed the basis of the World Health Organization (WHO) classification in 2008.[131-133] Careful analysis of these translocations and other recurring genetic abnormalities in leukemia patients has had a

profound impact on our understanding of the molecular genetic basis of leukemia (Fig. 51-2). Although many chromosomal abnormalities from AML blast cells have been identified and studied extensively, no single mutation has been shown to be sufficient to cause acute leukemia. These findings prompted Gilliland and colleagues[134-137] to propose what is now considered the classic "two-hit model" of AML pathogenesis. In this model, leukemic transformation results from distinct but collaborative sequential mutations in parallel molecular pathways that affect cell survival, proliferation, differentiation, and self-renewal. Class I mutations frequently involve an activated receptor or cytoplasmic-nuclear tyrosine kinase conferring a proliferative and/or survival ability to a specific cell but not affecting differentiation. By contrast, class II mutations specifically result in differentiation arrest and/or self-renewal and often involve key transcription factor oncogenes but alone do not confer a proliferative advantage. Although attractive, this model likely represents an oversimplification of AML pathogenesis. Initially, microarray studies and more recently, deep-sequencing approaches have revealed the presence of novel mutations and absence of tyrosine kinase lesions, particularly in normal karyotype AML, calling into question the general applicability of the "two-hit" model in all cases of AML. However, although the category of genetic lesions may not always subscribe to this classic paradigm, the number of "hits" required may be more universal. Genomic profiling of individual patient leukemias suggest that in some cases only two to three lesions are required for clonal evolution to frank AML, with fewer "hits" necessary in pediatric AML than in its adult counterpart.[129,138] Regardless, the prevalence of lesions categorized by the "two-hit" model will be outlined here, followed by more recent discoveries of novel genes implicated in AML pathogenesis and the variable frequency of these lesions in pediatric versus adult AML.

Class I Mutations

Among the earliest examples of class I mutations, *RAS* mutations were described in the early 1980s. There are three functional *RAS* gene family members—*NRAS, KRAS,* and *HRAS*—that all act as guanosine nucleotide phosphate (GTP)-binding proteins.[136] Mutations of *NRAS* are the most prominent *RAS* mutations in AML and have been found in as many as 30% of adult patients with AML.[139] Mutations, most frequently in codons 12, 13, and 61, result in the retention of the RAS protein in its active GTP-bound state and lead to the constitutive activation of downstream effector proteins, which causes the transcriptional activation of various target genes that direct cellular differentiation, proliferation, and survival (Fig. 51-3).[140] RAS proteins may be alternatively activated by mutations in genes encoding a number of regulatory factors. Activating point mutations in the *SHP-2/PTPN11* phosphatase provide a stimulatory signal through guanine nucleotide exchange factors, such as "Son of Sevenless" (SOS), resulting in increased RAS pathway signaling, as do inactivating mutations of neurofibromin-1 *(NF1)*, which codes for a GTPase-activating protein (GAP) of the same name.[141,142] NF1, normally functions, at least in part, by increasing the

Figure 51-3 Constitutive activation of the RAS pathway is central to myeloid leukemogenesis. RAS pathway signaling may be constitutively activated via a number of mutually exclusive mechanisms *(horizontal red arrows)*. These include the following: mutations in the GM-CSF or FLT3 surface receptors, resulting in ligand independent activation (found primarily in de novo AML); activating mutations in JAK2 (found in PV, ET, and PM) or SHP-2, c-CBL (found in JMML); activating mutations in RAS itself (found in all types of AML); or inactivating mutations in neurofibromin (found in JMML). *PV,* polycythemia vera; *ET,* essential thrombocytosis; *PM,* primary myelofibrosis; *FLT3,* fms-like tyrosine kinase 3; *GM-CSF,* granulocyte-macrophage colony-stimulating factor; *JAK2,* Janus 2 kinase; *JMML,* juvenile myelomonocytic leukemia. *(Modified from Loh ML, Vattikuti S, Schubbert S, et al: Mutations in* PTPN11 *implicate the SHP-2 phosphatase in leukemogenesis.* Blood *103:2325–2331, 2004; and Proytcheva M: Juvenile myelomonocytic leukemia.* Semin Diagn Pathol *28:298–303, 2011.)*

GTPase activity of RAS, thereby inactivating RAS-GTP by converting it into the inactive RAS-GDP form.[143] These three types of mutations function independently to activate RAS signaling and lead to disturbances in hematopoietic cell differentiation and proliferation that may ultimately contribute to the development of MDS, myeloproliferative disease (MPD), and AML (see Fig. 51-3).[144-146] Mutations in *NF1* and *PTPN11* have been particularly associated with JMML (see later).[142,147]

There has been significant disagreement regarding the prognostic implications of *RAS* mutations in MDS and AML. Several studies have demonstrated that *RAS* mutations in patients with MDS confer a poor prognosis and increase the risk for progression to acute leukemia.[148-155] Other studies have reported no difference in survival in AML patients who carried *RAS* mutations compared with patients without *RAS* mutations,[152] whereas some have suggested improved survival in patients with AML and *NRAS* mutations.[153] A large study of more than 2500 patients with AML demonstrated no difference in prognosis in patients with or without *RAS* mutations. This study also demonstrated an association between *RAS* mutations and a leukemia karyotype containing inv(16), a class II mutation resulting in the CBFβ-MYH11 fusion protein and altered function of the core-binding factor (CBF) transcriptional complex.[156] A recent report from the COG examining 825 pediatric AML samples treated on two recent trials identified *NRAS* mutations in 10% of patients predominantly in codons 12 and 13, with no mutations in codon 61. Interestingly, most of these mutations were associated with good prognosis *NPM1* mutations (see later) and not CBF alterations. However, multivariate analysis confirmed a lack of independent impact of *NRAS* mutations on prognosis.[157]

Another group of class I mutations involves constitutive activation of receptor or cytoplasmic-nuclear tyrosine kinases. The *BCR-ABL* translocation that is the sine qua non of CML is an example of a class I mutation causing the activation of the ABL tyrosine kinase. Similarly, receptor tyrosine kinase mutations activate the human protooncogenes *KIT* and *FLT3* in AML. The KIT protein is activated by the binding of its ligand stem cell factor and is critical for the development and growth of mast cells, melanocytes, HSCs, and the interstitial cells of Cajal.[158] Mutations in *KIT* allow ligand-independent activation of KIT and confer factor-free growth and tumorigenicity in hematopoietic cell lines.[159,160] Blasts from patients with AML express KIT on their cell surfaces in most cases.[161-163] Deletional and insertional mutations of *KIT* have been identified in the blast cells of patients with AML, often in association with the CBF abnormalities inv(16) or t(8;21).[164]

The *FLT3* gene encodes a class III fms-like receptor tyrosine kinase expressed in early hematopoietic progenitors. *FLT3* mutations occur in two varieties, internal tandem duplications (ITDs) in the juxtamembrane region and activation loop mutations (ALMs), primarily at codons 835 and 836. The *FLT3*-ITD is one of the most frequent abnormalities in adult AML, documented in 25% to 30% of patients,[165-169] and generally confers a poor prognosis.[170,171] By contrast, ALMs occur in only 10% of adult patients and have not been associated with inferior survival rates. *FLT3*-ITDs have been observed in 5% to 16% of pediatric AML cases and ALMs in 2% to 5% of cases. Paralleling the adult studies, *FLT3*-ITDs, but not ALMs, were associated with a poor prognosis in children.[172-175] *FLT3*-ITDs result in the constitutive activation of FLT3 and cause interleukin-3–independent growth in Ba/F3 and 32D cells.[165,168,176] This activation, in turn, results in the signaling of multiple downstream pathways, including the aforementioned RAS pathway, and the inhibition of caspase-mediated apoptosis through the stimulation of phosphatidylinositol 3′-kinase (PI3K) and AKT (see Fig. 51-3). However, mice transplanted with FLT3-transformed hematopoietic cells develop a myeloproliferative disorder characterized by splenomegaly and leukocytosis but they do not develop AML.[177] *FLT3*-ITDs often occur in conjunction with other mutations, including *NPM1* (see later) and *WT1* (see later).[178]

Class II Mutations

In class II mutations, the molecular defect appears to be at the level of transcriptional activation, whereby transcriptional repressors cause a dominant negative inhibition of normal hematopoietic cell differentiation. AML can be subtyped based on the type of class II mutations in the blast cells of patients. The type 1 subset of class II mutations occurs in patients with de novo AML. These are typical chromosomal translocations resulting in chimeric oncoproteins that in some cases may cause the inhibition of differentiation. The type 2 subset of class II mutations usually are found in patients with AML arising after a prodrome of MDS and manifest more commonly in older adults or in patients who have received previous chemotherapy. Cytogenetic studies of the blast cell populations in these patients have complex karyotypes, lacking translocations but harboring deletions such as 5q–, monosomy 7, and 20q–.

Type 1 Mutations

Translocations Involving Core-Binding Factor Complex. Several of the translocations that have been identified in adult and childhood de novo AML involve the CBF complex. The CBF complex is the most frequent target of chromosomal translocations in the human leukemias. The CBF regulatory complex consists of a DNA-binding subunit, RUNX1 (also called CBFα or AML1) and CBFβ, a subunit that does not bind DNA independently but heterodimerizes with RUNX1 or one of its closely related family members.[179] Chromosomal translocations that modify the CBF complex in AML include the following: t(8;21)(q22;q22), which generates the AML1-ETO fusion protein, more recently referred to as RUNX1-RUNX1T1 (Fig. 51-4); t(3;21)(q26;q22), which gives rise to AML1-EVI1; and inv(16)(p13;q22), which fuses the CBFβ to smooth muscle myosin heavy chain (SMMHC), resulting in the *CBFB-MYH11* fusion gene. The *AML1* gene was inactivated in the germline of mice and was shown to be essential for definitive hematopoiesis of all cell lineages.[180,181] Homozygous animals die early in embryogenesis of central nervous system (CNS) hemorrhage, but they have normal morphogenesis and yolk sac hematopoiesis lineages.[180,181] Inactivation of the *CBFβ* gene in the mouse has shown a similar phenotype in the homozygous null mice.[179,182] These experiments have demonstrated that the AML1/CBFα complex is essential for normal hematopoiesis and that chromosomal rearrangements involving this complex may interfere with its regulatory function in ways that lead to disruption of cellular differentiation, and eventually malignant transformation.

Evidence primarily from knock-in studies in mice has supported the hypothesis that the AML1-ETO fusion protein functions as a dominant negative inhibitor of wild-type functions.[183-185] In these experiments, the *AML1-ETO* fusion gene is “knocked in” to the wild-type

AML1 locus. The phenotype of these mice is identical to the *AML1* knockout; the mice die early in embryogenesis from CNS hemorrhage and lack any evidence of definitive hematopoiesis, although the rare cells that survive and express AML1-ETO have an increased capacity for self-renewal.[185] Biochemical experiments have shown that the ETO portion of the AML1-ETO chimeric protein recruits nuclear corepressor complexes to the CBF promoters, resulting in transcriptional inhibition of target genes normally activated by the AML1/CBFβ heterodimeric complex (see Fig. 51-4D).[186,187] Subsequent studies using inducible murine model systems to bypass the embryonic lethality of *AML1-ETO* overexpression have demonstrated that overexpression of this transgene at later developmental time points confers enhanced self-renewal capacity to bone marrow progenitors, as demonstrated by serial culture experiments. Importantly, the mice do not develop AML but appear to be predisposed to leukemogenesis. Thus after treatment with *N*-ethyl-*N*-nitrosourea (ENU), the mice developed rapid onset of AML compared with similarly exposed wild-type mice. Moreover, as noted, there is an association in myeloid leukemia of *AML1-ETO* translocations and mutant tyrosine kinases, such as KIT.[188] Interestingly, *AML1-ETO* transcripts may persist for a long time in patients with *AML1-ETO*–expressing AML in sustained remission.[189]

Translocations Involving the Retinoic Acid Receptor-α. Reciprocal chromosomal translocations involving the retinoic acid receptor-α *(RARA)* gene locus on chromosome 17 are the defining molecular features of acute promyelocytic leukemia (APL). Before the *RARA* translocations were described, retinoic acid was known to induce myeloid differentiation in vitro[190] and therapy with all-*trans*-retinoic acid (ATRA) in patients with APL was shown to induce complete remission (CR).[191] The intense investigation of the *RARA* gene triggered by these observations culminated in identification of the promyelocytic leukemia PML-RARA translocation breakpoint, t(15;17)(q22;q11), reported simultaneously by several groups.[192-197] Although most APL cases have the associated t(15;17), other reciprocal translocations involving the *RARA* gene have been identified in which the gene is fused to other gene partners. The most common of these include the promyelocytic leukemia zinc finger *(PLZF)* gene on chromosome 11 in t(11;17)(p13;q11) and the nucleophosmin gene *(NPM)* on chromosome 5 in t(5;17)(q31;q11).[198,199]

Normally RARA functions as a ligand-dependent activator of transcription.[200] It forms a heterodimer with the related protein, retinoid X receptor (RXR),[201] and binds through its zinc finger domain to a specific promoter sequence; in the presence of the retinoic acid ligand, the RARA-RXR heterodimer activates transcription of retinoic acid–responsive genes.[194] This process is accomplished in concert with a coactivator complex that includes proteins such as p300 and pCAF. In the absence of retinoic acid, a corepressor complex is recruited, composed of N-CoR (nuclear receptor corepressor) or SMRT (silencing mediator of retinoid and thyroid receptors), which binds to another protein called Sin3 and then to HDAC1.[199,202-204] HDAC1 is a histone deacetylase protein, which epigenetically alters histones to keep DNA in an untranscribable form. The expression of retinoic acid–responsive genes is essential for normal myeloid development.[205]

Much evidence supports the hypothesis that the PML-RARA fusion protein functions as a dominant negative inhibitor of the PML protein and RXR. PML proteins are normally located in macromolecular nuclear organelles, called PML oncogenic domains (PODs).[206] The PML-RARA fusion protein disrupts the PODs, causing normal PML, RXR, and other nuclear proteins to disperse in an abnormal pattern.[207,208] ATRA and arsenic trioxide (As_2O_3)[209] have shown activity in APL blast cells and in patients with APL, and studies of these drugs have afforded important insights into the mechanisms of leukemogenesis in APL.[191,210-212] ATRA and As_2O_3 appear to act through different biochemical pathways, and promyelocytes resistant to ATRA are often sensitive to treatment with As_2O_3. Both drugs induce degradation of the PML-RARA fusion protein but through different mechanisms. Retinoic acid binding to wild-type retinoic acid receptors (RARs) in the cell nucleus causes degradation of the PML-RARA protein through the ubiquitin-proteosome and caspase systems, thus allowing for the terminal differentiation of leukemic promyelocytes.[213-215]

This binding also results in derepression whereby N-CoR is dissociated from the PML-RARA fusion protein and, subsequently, the nuclear coactivator complex is recruited to reverse histone deacetylase-mediated repression. PODs are relocated back to the normal nuclear pattern.[208,216] By contrast, As_2O_3 appears to target the PML portion of the PML-RARA fusion protein preferentially and causes its degradation by inducing apoptosis,[217] potentially through downregulation of the antiapoptotic factor BCL2.[213,218,219] The activity of these agents has led to the inferences that fusion proteins may interfere with normal myeloid cell development in several ways—through inhibitory effects on assembly of the PODs that contain PML or through dominant inhibitory effects on transcriptional targets of dimeric complexes with normal retinoid receptors, leading to arrest of differentiation at the promyelocyte stage.

Studies using transgenic mice have shown that the PML-RARA fusion product is involved in the development of leukemia. Transgenic mice generated with the PML-RARA fusion protein specifically expressed in the myeloid-promyelocytic lineage develop a myelodysplastic-like disorder during the first year of life.[220,221] A subset of these mice then develops a form of acute leukemia that closely mimics human APL and responds to ATRA. Given the relatively long latency period and the development of leukemia in only a fraction of the mice, it is likely that the PML-RARA translocation is insufficient by itself to cause APL and that second mutations are necessary for leukemic transformation.

Mixed-Lineage Leukemia Gene Translocations. Transcriptional coactivators and corepressors have been implicated in leukemogenesis.[134] An example is the myeloid-lymphoid or MLL protein, a large protein containing transcriptional activation and repression domains, which is believed to act epigenetically to modulate gene expression through its effects on chromatin structure and configuration. Wild-type MLL is required for normal hematopoiesis and HSC development.[222] Mice deficient in MLL die on embryonic day 10.5 and have numerous skeletal, neural, and hematologic deficits. Heterozygous mice have defects in embryonic segmentation and yolk sac hematopoiesis, and adults demonstrate a mild anemia and thrombocytopenia.[223,224] Chromosomal translocations of the *MLL* gene on chromosome segment 11q23 have been identified in human AML and ALL and confer a poor prognosis.[225,226] Many gene partners have been identified that are involved in these translocations, including *AF4, AF9, ENL, AF6, ELL*, and *AF10*. In most cases, the fusion proteins incorporate the 5′ end of *MLL* and the 3′ end of the partner.[227,228] Despite the number of different fusion partners, leukemias with *MLL* translocations tend to possess a distinct genetic signature compared with AML and ALL samples lacking an *MLL* translocation. This genetic signature includes the upregulation of a number of specific *HOX* family genes, including *HOXA9, HOXA7,* and *MEIS1*.[225,229-231] Wild-type *MLL* is known to play a major role in *HOX* gene transcriptional regulation.[232] In turn, *HOX* genes play critical roles in embryonic development and normal hematopoiesis. A number of studies have clearly demonstrated that overexpression of specific major *HOX* genes in mouse models and human bone marrow samples, whether by involvement in reciprocal translocations or by gene upregulation, is linked to the transformation of malignant HSCs in AML.[233-241] The mechanism whereby MLL fusion proteins upregulate *HOX* gene expression may differ, depending on whether the fusion partner encodes a nuclear partner with direct transcriptional activity or a cytoplasmic protein that results in MLL protein dimerization and subsequent transcriptional activation.[112]

Transcriptional control may be mediated through the modification of histone proteins, which function to maintain chromatin structure. Recently, the DOTL1 complex was identified as a critical factor in MLL-induced leukemogenesis.[242] DOT1L is a histone-3-lysine-79 (H3K79) methyltransferase, which was previously believed to play a fairly ubiquitous role in methylating gene targets in concert with transcription. However, Zhang and Armstrong's group definitively demonstrated through a series of elegant in vitro and in vivo experiments a specificity for DOT1L in the epigenetic regulation of MLL-translocated downstream targets. When DOT1L was knocked out or absent from *MLL-AF9*–transformed cell lines or transgenic mice, leukemia was prevented.[242-244] The *MLL* gene is rearranged in up to 20% of pediatric cases of AML.[245] Translocations of *MLL* are the single most common genetic alteration in infants with acute leukemia, regardless of phenotype, and account for approximately 70% of all cases of AML and ALL in infants.[246] In pediatric and adult cases of AML, the presence of the 11q23 translocation is generally associated with an unfavorable prognosis.[247]

Although less common than *MLL* translocations, the *MLL* gene can be altered by partial tandem duplications (PTDs) of particular exons. These PTDs occur in adult and pediatric AMLs with a normal karyotype, as well as those with trisomy 11. Similar to *MLL* fusions, the *MLL*-PTD tends to be associated with a poor prognosis and often with the presence of an *FLT3* mutation. The mechanisms underlying MLL-PTD leukemogenesis have not yet been elucidated but appear to be different than those of *MLL* fusions.[228,248] Interestingly, *MLL*-PTD appears to repress wild-type *MLL* expression, which may be an important feature underlying the leukemogenic potential of this abnormality.[248]

Type 2 Mutations. The leukemogenic mutations discussed in the previous sections involve balanced translocations, duplications, or substitutions that appear to disrupt regulatory mechanisms controlling hematopoiesis and result in dysregulated cell differentiation. Another group of mutations involve unbalanced chromosome rearrangements, such as chromosome loss (e.g., monosomy 5, monosomy 7) or large chromosomal deletions (e.g., 5q−, 7q−, 20q−).[249,250] These mutations may lead to leukemic transformation by the loss of a tumor suppressor gene (or genes), which then confers a differentiation block and growth advantage to the mutated cells.[251] Identification of these putative tumor suppressor genes has been problematic because the deleted regions are usually large and include many candidate genes. Moreover, leukemogenesis is triggered by the gene's inactivation rather than by altered structure, making the abnormal gene difficult to identify. However, α-catenin has been identified by our group as a novel tumor suppressor gene on the proximal region of the long arm of chromosome 5.[252] Non–therapy-related AML with these chromosomal losses or deletions occurs most commonly in older patients and is often associated with the prodrome of MDS. In the pediatric population, this class of cytogenetic abnormality is uncommon and is also frequently preceded by MDS.[253] Monosomy 7 is the most frequent chromosomal abnormality documented in children with MDS and is sometimes the sole detectable cytogenetic abnormality.[254,255] Overall, chromosome loss represents about half of the chromosomal abnormalities identified in MDS.[253]

Therapy-Related AML. Chromosomal loss and large chromosomal deletions are common in therapy-related AML in the adult and pediatric populations. Although most cases of MDS and AML arise de novo, without evidence of any leukemogenic exposure, in 10% to 20% of patients the disease arises after previous exposure, particularly to topoisomerase II inhibitors, alkylating agents, and ionizing radiation.[256] The 11q23 translocations producing *MLL* gene fusions are common cytogenetic abnormalities in patients who develop AML after therapy with topoisomerase II inhibitors (e.g., epipodophyllotoxins).[6,7,257] AML developing after the use of topoisomerase II inhibitors has a short median latency period of 30 to 34 months, is usually FAB classification M4 or M5, and lacks the antecedent prodrome of MDS.[258] The blast cells of patients with AML or MDS occurring after exposure to alkylating agents often have large chromosomal losses or deletions and have a poor prognosis.[256,259,260] The most common chromosomal abnormalities in such cases involve chromosome 7 and chromosome 5. In contrast to the therapy-related AML with *MLL* fusion genes that develops after treatment with topoisomerase II inhibitors, MDS or AML related to therapy with alkylating agents typically develops after a longer median latency period, 3 to 5 years from the alkylator exposure. Mutations in the *TP53* tumor suppressor gene have been previously linked to therapy-related AML and were believed to be infrequent in de novo cases. However, more recently, *TP53* mutations have been found to be common in de novo AML with a complex karyotype. In both contexts there is an association with chromosome 5 and 7 copy number alterations.[261-264]

AML with a Normal Karyotype. Chromosomal abnormalities have provided some understanding of the mechanisms of malignant transformation in leukemia. However, in many cases of de novo leukemia, no chromosomal abnormality can be detected and the mechanism behind leukemogenesis in these cases is unknown. Because AML involves a block in myeloid differentiation, evidence for mutations in key transcription factors involved in normal myelopoiesis has been sought. Mutations in the early myeloid transcription factors PU.1 and CCAAT/enhancer-binding protein α (C/EBPα) have been identified in a number of AML subtypes and are generally not associated with a known chromosomal translocation.[265] Mouse models have demonstrated that the degree of transcription factor knockdown is critical to the particular phenotype. Mice expressing PU.1 at 20% of normal levels develop AML, whereas those with complete knockdown or 50% of normal levels do not.[266] GATA1, a critical transcription factor for erythrocyte and megakaryocyte development, is mutated in nearly all cases of acute megakaryoblastic leukemia associated with Down syndrome (see later).[267]

Expression profiling using microarrays first used to distinguish prognostic tumor subclasses in breast carcinoma[268-271] and large B-cell lymphoma[272] has also been applied to leukemia.[233] Using this technology, a set of 50 genes was sufficient to discriminate ALL from AML. More recent validation of this technique in AML has demonstrated the correlation between gene expression profiling studies and the prognostic classification of human AML based on cytogenetic abnormalities.[273] Gene expression profiling has provided valuable new insights into the identification of prognostic subclasses in adult[274] and pediatric[275] AML with a normal karyotype.

Our understanding of the molecular mechanisms underlying de novo AML with a normal karyotype was advanced by the finding of mutations involving the *NPM* gene in 35% of cases of adult AML and 60% of cases with a normal karyotype.[276] This frequency supersedes the incidence of *FLT3* mutations and has established *NPM* mutations as the most frequent genetic abnormality in adult AML. The frequency of *NPM* mutations is lower in pediatric AML, occurring in only 6% to 8% of all pediatric patients with AML, but also occurs in a higher number of pediatric patients with a normal karyotype (approximately 27%).[277,278] The *NPM* gene on chromosome 5q was previously well known as a partner in a number of oncogenic translocations, including *NPM-ALK* (anaplastic lymphoma kinase) in anaplastic large cell lymphoma and *NPM-RARA* in APL. NPM is a molecular chaperone that shuttles between the cytoplasm and nucleus but is found most prominently in nucleoli. It has been shown to function in the prevention of protein aggregation in the nucleolus and the regulation of preribosomal particles through the nuclear membrane. It has also been shown to play a role in the regulation of the alternate reading frame (ARF)-TP53 tumor suppressor pathway. *NPM* mutations are heterogeneous but occur predominantly in exon 12, uniformly affecting the C-terminal of the protein and causing the formation of a neomorphic nuclear export signal in the resulting NPMc protein. This results in a shift of NPM localization, sequestering it exclusively to the cytoplasm. *NPM* mutations occur more frequently in children older than 10 years and, as is the case in adults, tend to be associated with a good prognosis. However, there has been a strong association established between patients with *NPM* mutations and *FLT3*-ITDs, which portend a poor prognosis. Patients with both these abnormalities do not fare as well as those with *NPM* mutations alone.

Similarly, mutations in *CEBPA* have been associated with a good outcome. *CEBPA* encodes the CCAAT/enhancer binding protein-alpha (C/EBPα), which functions as a transcription factor that plays a major role in terminal granulocytic differentiation as well as influencing proliferation. C/EBPα is a basic region leucine zipper transcription factor consisting of two amino-terminal transactivation domains, a basic DNA-binding region, and a carboxyl-terminal leucine zipper. Mutations in pediatric AML commonly occur in the amino-terminal domain and bZip domain of the leucine zipper, and many patients harbor both types of mutations.[279]

Mutations in the Wilms tumor 1 (WT1) transcription factor have been identified in approximately 10% of adult and childhood AML, predominantly in patients with a normal karyotype.[280-284] Mutations are common in exons 7, 8, and 9, comprising three of the four zinc fingers of *WT1*. *WT1* mutations frequently occur together with *FLT3*-ITDs; however, in contrast to the adult studies, they do not independently confer a poor prognosis.[285] Recently, a number of large genomic studies using next-generation sequencing technology revealed novel frequent mutations in DNA methyltransferase 3A (DNMT3A) and IDH1 and IDH2 in adult normal karyotype AML.[128,286,287] In adult disease, these mutations confer a poor outcome. By contrast, these mutations are relatively rare in pediatric AML but similarly occur more commonly in patients with a normal karyotype, highlighting the different molecular spectrum of disease in adult and childhood counterparts.[288-290]

Morphology and Cytochemistry

The initial diagnosis of AML relies on accurate interpretation of the cellular morphology of the bone marrow smears. The diagnosis usually can be made based on the morphologic characteristics of the blasts in a Wright-Giemsa–stained bone marrow smear (Fig. 51-5). In addition to general morphology, the diagnosis can be confirmed in cases exhibiting Auer rods (thin, needle-shaped cytoplasmic deposits that stain pink with Wright-Giemsa and are strongly myeloperoxidase [MPO]-positive). In addition to examination of the morphology of the blasts, the Wright-Giemsa stain is also used to assess for dysplastic features in erythroid, myeloid, and megakaryocytic cell lines.

Additional cytochemical stains are important for the accurate diagnosis of AML. MPO and Sudan black B (SBB) are cytochemical stains for granulocyte, eosinophil, and monocyte lineages. Peroxidase is present in the primary granules of myeloid cells, beginning at the promyelocyte stage and throughout subsequent maturation. Typically, leukemic myeloblasts are also strongly peroxidase-positive. MPO staining of Auer rods is particularly robust in leukemic blasts and can demonstrate Auer rods not recognized using the Wright-Giemsa stain. By contrast, the MPO staining of monoblasts shows a fine granular pattern in the monoblast cytoplasm. The staining pattern of SBB is similar to that of peroxidase, particularly in myeloblasts and in the detection of Auer rods. Monoblasts either do not stain or show a weakly positive, diffuse pattern with SBB.

The esterase stains are useful for distinguishing granulocytic cells from cells of the monocytic lineage. Chloroacetate esterase is a specific stain for granulocytes and mast cells. Results of staining of early myeloblasts are often negative, but promyeloblasts and later granulocytic lineage cells stain strongly, as do Auer rods. Monoblasts do not stain with chloroacetate esterase. In contrast, the nonspecific esterases (NSEs) such as α-naphthyl butyrate esterase and α-naphthyl acetate esterase stain monoblasts and monocytes strongly. Granulocytic and lymphoid cells do not stain with the nonspecific esterases. The blast cells of AML-M4 (i.e., myelomonocytic leukemia) should demonstrate positive chloroacetate esterase activity and α-naphthyl butyrate esterase or α-naphthyl acetate activity; this finding is important for making the diagnosis. The periodic acid–Schiff (PAS) reaction is not as informative as the previously described stains, but it can be useful, particularly in the diagnosis of AML-M6 (i.e., erythroleukemia). Leukemic erythroblasts can stain strongly with PAS, whereas normal erythroid precursors generally demonstrate no PAS activity.

Immunophenotype

Since the 1980s, multiparameter flow cytometric analysis has become an important element in the diagnosis and classification of leukemia. More recently, multiparameter flow cytometry has been used as a tool to detect MRD in acute myeloid leukemia and is being incorporated into clinical trials to clarify prognostic groups and help make treatment decisions.[291-300] Immunophenotyping using a large panel of monoclonal antibodies to myeloid and lymphoid lineage and progenitor cell–associated antigens has been used to discriminate myeloid or lymphoid differentiation correctly in up to 98% of patients.[301,302] Monoclonal antibodies have been classified based on their reactivity with the lineage or differentiation-associated antigens on the surfaces of normal and malignant cells. Because the monoclonal antibodies are not leukemia cell–specific and most of the hematopoietic antibodies are not strictly lineage specific, it is necessary to use panels of antibodies on blast cell populations and to incorporate the immunophenotypic information with the clinical findings and other morphologic, cytochemical, and cytogenetic results for accurate leukemia cell classification.

Blasts of myeloid origin generally express HLA-DR, CD33, and CD34. Monocytic cells usually express HLA-DR at all stages of maturation, whereas promyelocytes and more mature cells of the granulocyte lineage do not. CD33 and CD13 are expressed on neutrophil and monocyte precursors, but CD33 is absent on mature neutrophils. CD14 is relatively specific for cells of the monocytic lineage. As myeloid differentiation continues, CD15 expression increases, whereas CD34 expression decreases. Megakaryocytic cells and platelets express CD41, CD42, and CD61.

Immunophenotyping has been particularly valuable for lineage assignment in undifferentiated leukemias (i.e., AML-M0), identification of acute megakaryocytic leukemia, and analysis of the lineage of leukemias with *MLL* gene translocations.[303-308]

Cytogenetics

Cytogenetic analysis is an essential component in the diagnosis and treatment of AML. The chromosomal aberrations detected by cytogenetic testing also have prognostic value and may be used as tumor markers. In

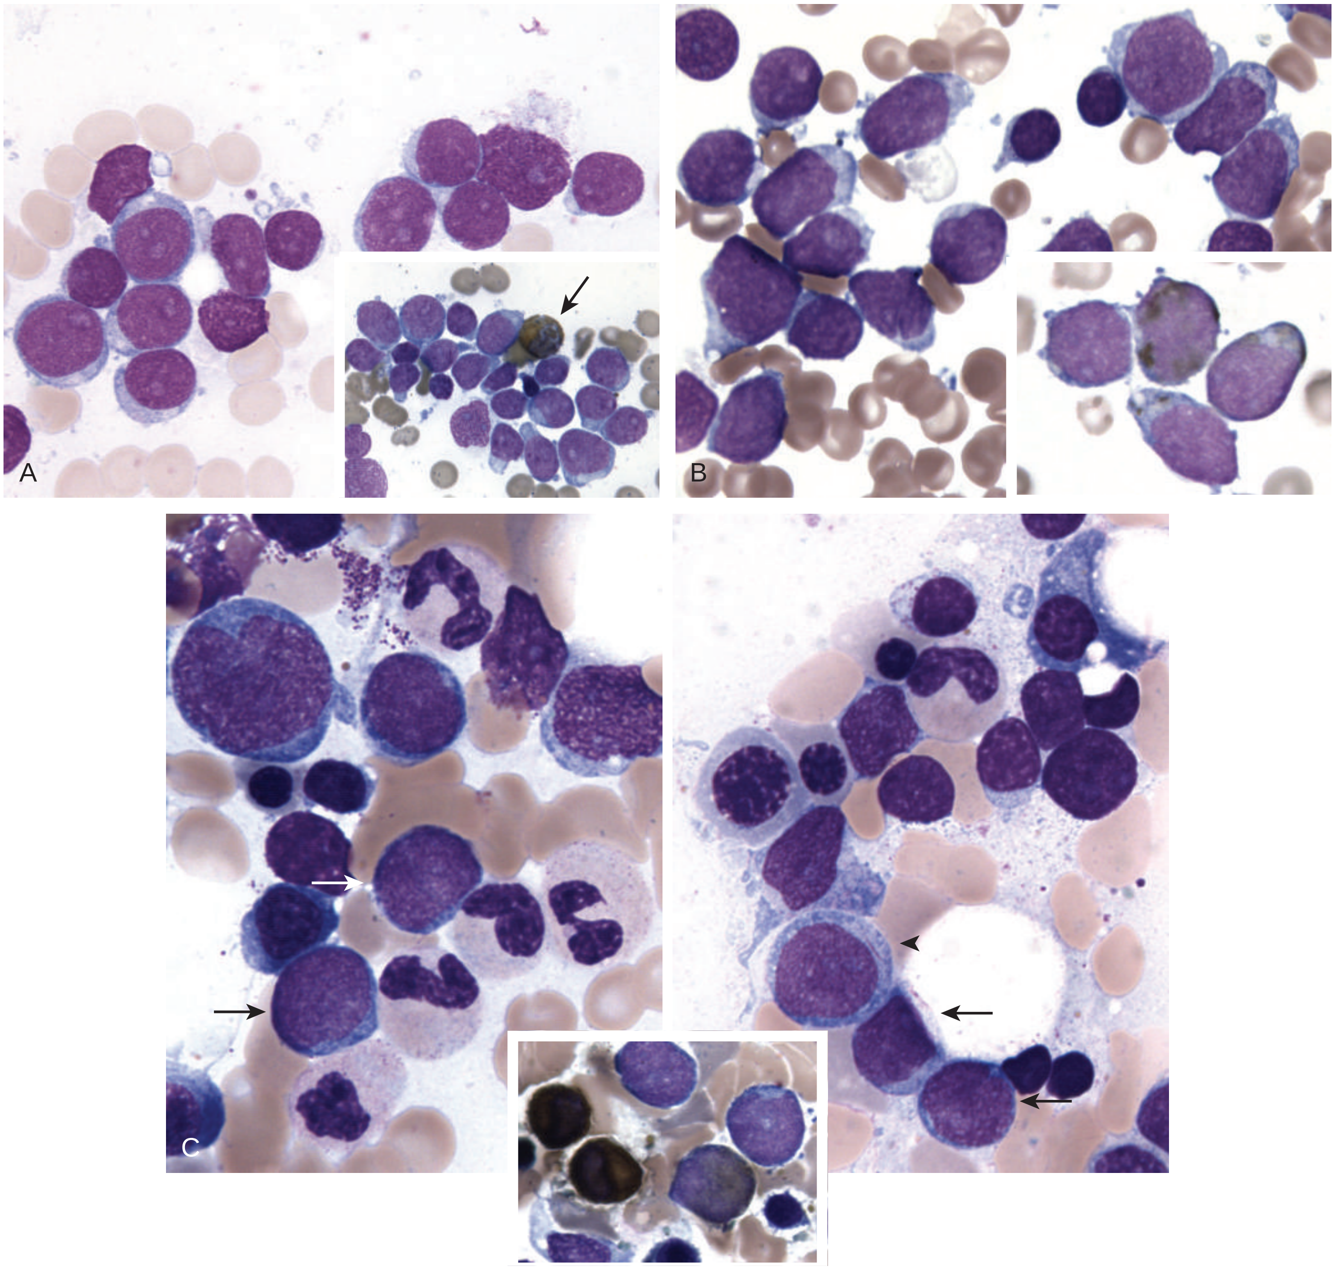

Figure 51-5 Subtypes of acute myeloid leukemia. All images are from Wright-Giemsa–stained bone marrow aspirate smears, except where otherwise designated. **A,** Acute myeloblastic leukemia, minimally differentiated. The blasts may vary in size but have round to oval nuclei, variably prominent single or multiple small nucleoli, and scant cytoplasm that is agranular. *Inset,* The blasts here show no reactivity for myeloperoxidase, although rare reactivity (<3% blasts) may be seen; a neutrophil *(arrow)* serves as a positive internal control. **B,** Acute myeloblastic leukemia, without maturation. Blasts generally predominate within the marrow and comprise 90% or more of nonerythroid cells. The blasts may contain cytoplasmic granules and occasional Auer rods or may resemble lymphoblasts. *Inset,* Myeloperoxidase positivity is present in more than 3% of blasts, although the reactivity itself is of varied intensity. **C,** Acute myeloblastic leukemia, with maturation. Blasts comprise 20% or more of marrow cellularity *(arrows),* whereas maturing neutrophils (e.g., promyelocytes, myelocytes, metamyelocytes, bands, and neutrophils) constitute 10% or more of nucleated elements. Dysmyelopoiesis may be evident. Auer rods are commonly present and may be long and tapered *(arrowhead). Inset,* Myeloperoxidase shows variable reactivity in a subset of the blasts (>3%) and strong reactivity in the maturing neutrophilic forms.

the WHO classification of hematologic malignancies, specific cytogenetic abnormalities have been included in the diagnostic and prognostic criteria for differentiating subclasses of AML.[309]

Cytogenetic analyses of bone marrow samples have revealed chromosomal abnormalities in most patients with AML.[310-317] In the pediatric population, the incidence of cytogenetic abnormalities is even higher than that in adults.[245,310,318] However, the distribution of the specific cytogenetic abnormalities is different in the various age groups. In infants with AML, the most common chromosomal aberrations are translocations

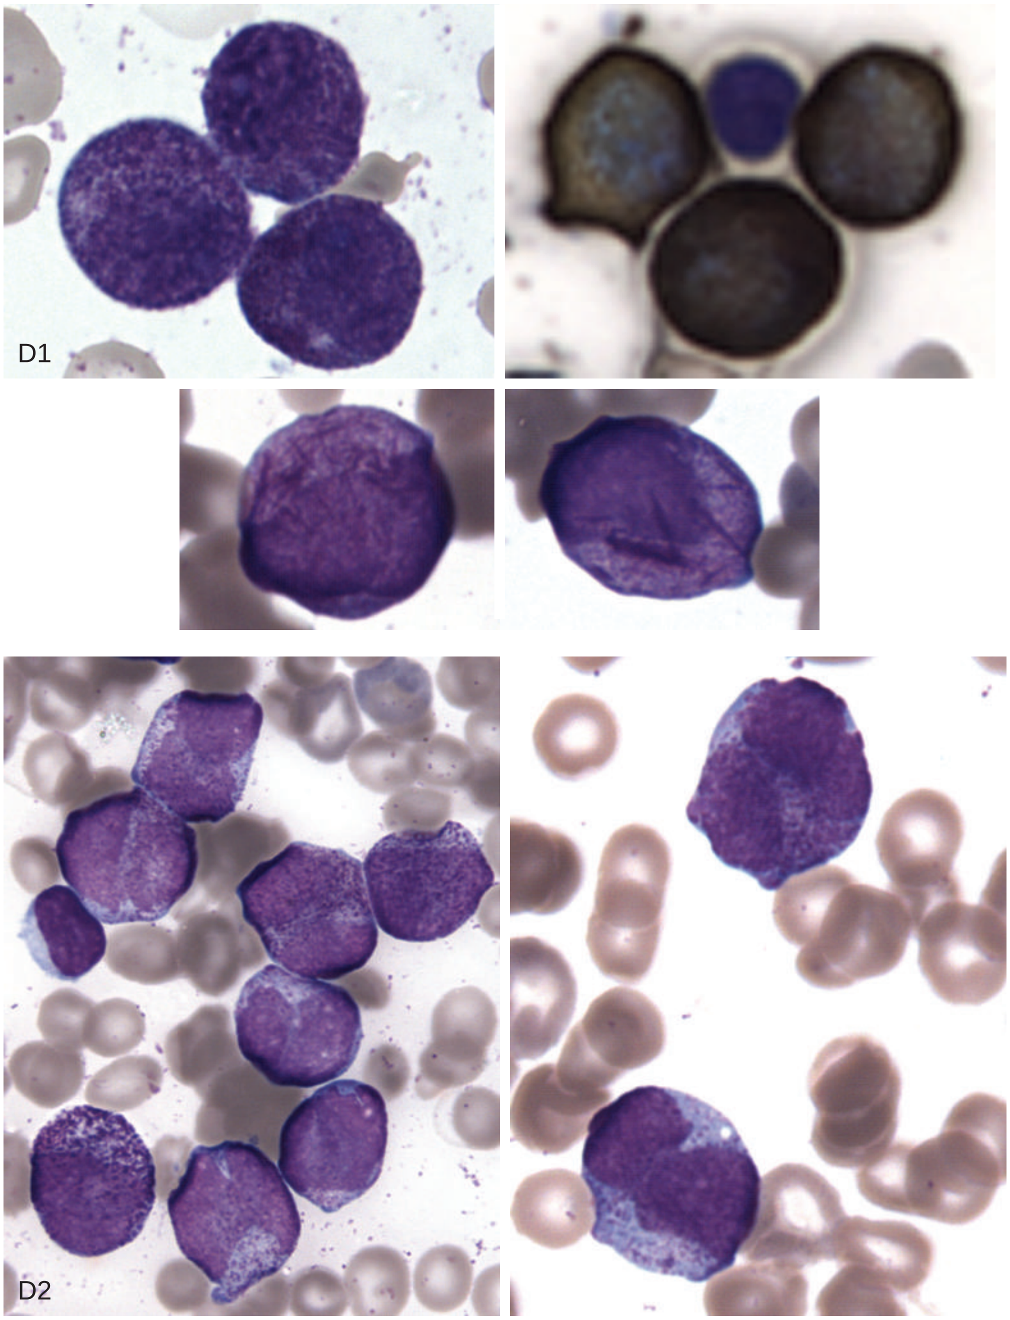

Figure 51-5, cont'd **D1,** Acute promyelocytic leukemia (hypergranular variant). Malignant promyelocytes have eccentric nuclei, prominent nucleoli, and abundant cytoplasm, with intense azurophilic granules. Varied numbers of promyelocytes may contain multiple Auer rods, a characteristic finding *(lower panels)*. Myeloperoxidase shows intense reactivity in the promyelocytes that largely obscures the nucleus *(upper right panel)*. **D2,** Acute promyelocytic leukemia (microgranular variant). These malignant promyelocytes have a bilobed or butterfly-shaped nucleus, fine chromatin, variably prominent nucleoli, and abundant cytoplasm, with sparse to numerous azurophilic granules. Myeloperoxidase shows intense reactivity in these variants similar to that seen in the hypergranular forms.

involving the *MLL* gene (band 11q23).[319-321] The incidence of 11q23 translocations is as high as 40% in AML blasts of children younger than 2 years. After age 2 years, the frequency of 11q23 translocations decreases with age, and the translocation is detectable in AML blasts from less than 10% of older children and adults.[132,245,310,318] One rare chromosomal abnormality, the t(1;22)(p13;q13), is found almost exclusively in non–Down syndrome infants with acute megakaryocytic leukemia. In a published review of 39 patients with this translocation, 95% were younger than 2 years, and it was not identified in adults with AML.[322] This translocation is now known to

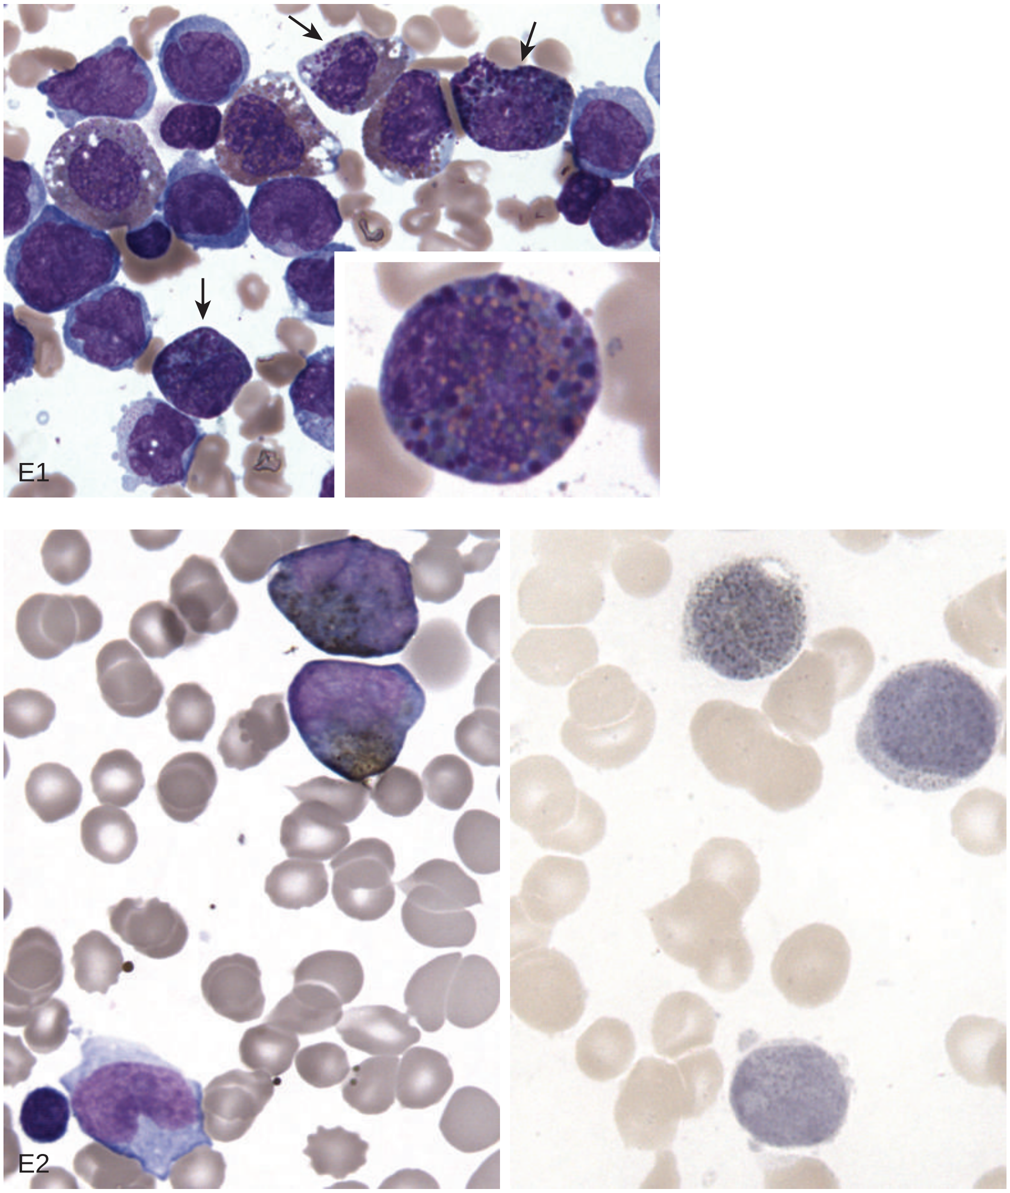

Figure 51-5, cont'd **E1,** Acute myelomonocytic leukemia with eosinophilia. Blasts, maturing neutrophils, and maturing monocytes each constitute 20% or more of marrow cellularity. Additionally, abnormal eosinophils are present in all stages of maturation and contain enlarged granules that are purple-violet as opposed to orangeophilic *(arrows; inset).* E2, Acute myelomonocytic leukemia with eosinophilia (cytochemistries). At least 3% of blasts show myeloperoxidase reactivity *(left),* whereas monoblasts, promonocytes, and monocytes exhibit nonspecific esterase reactivity that may be weak, as seen in this case *(right).*

result in aberrant expression of the *OTT-MAL* fusion gene.[323]

There are two classification systems for AML (see next section). The FAB classification is based exclusively on morphology. However, there are some morphologic subtypes such as M3 and M4eo that are always associated with particular cytogenetic changes, that is, *RARA* rearrangements for the former and inv(16) or t(16;16) in the latter. In addition, there are certain cytogenetic changes that are often (if not exclusively) associated with a particular subtype and that carry prognostic significance, such as the good prognosis t(8;21) often associated with the M2 subtype or *MLL* rearrangements often associated with the M5 subtype. The WHO classification system takes this into account and has a category of "acute myeloid leukemia with recurrent genetic abnormalities," which includes t(8;21), inv(16) or t(16;16), t(15;17), and 11q23. The fusion proteins thus generated are discussed in more detail earlier (see "Acute Myelogenous Leukemia: Biology"). Some of the more common chromosomal abnormalities and their associated FAB and WHO subtypes are shown in Table 51-1 and Box 51-2. The prognostic significance of certain cytogenetic abnormalities is discussed later (see "Prognosis").

French-American-British Classification

In 1976, the FAB group proposed a system of classification of AML based on morphologic and cytochemical

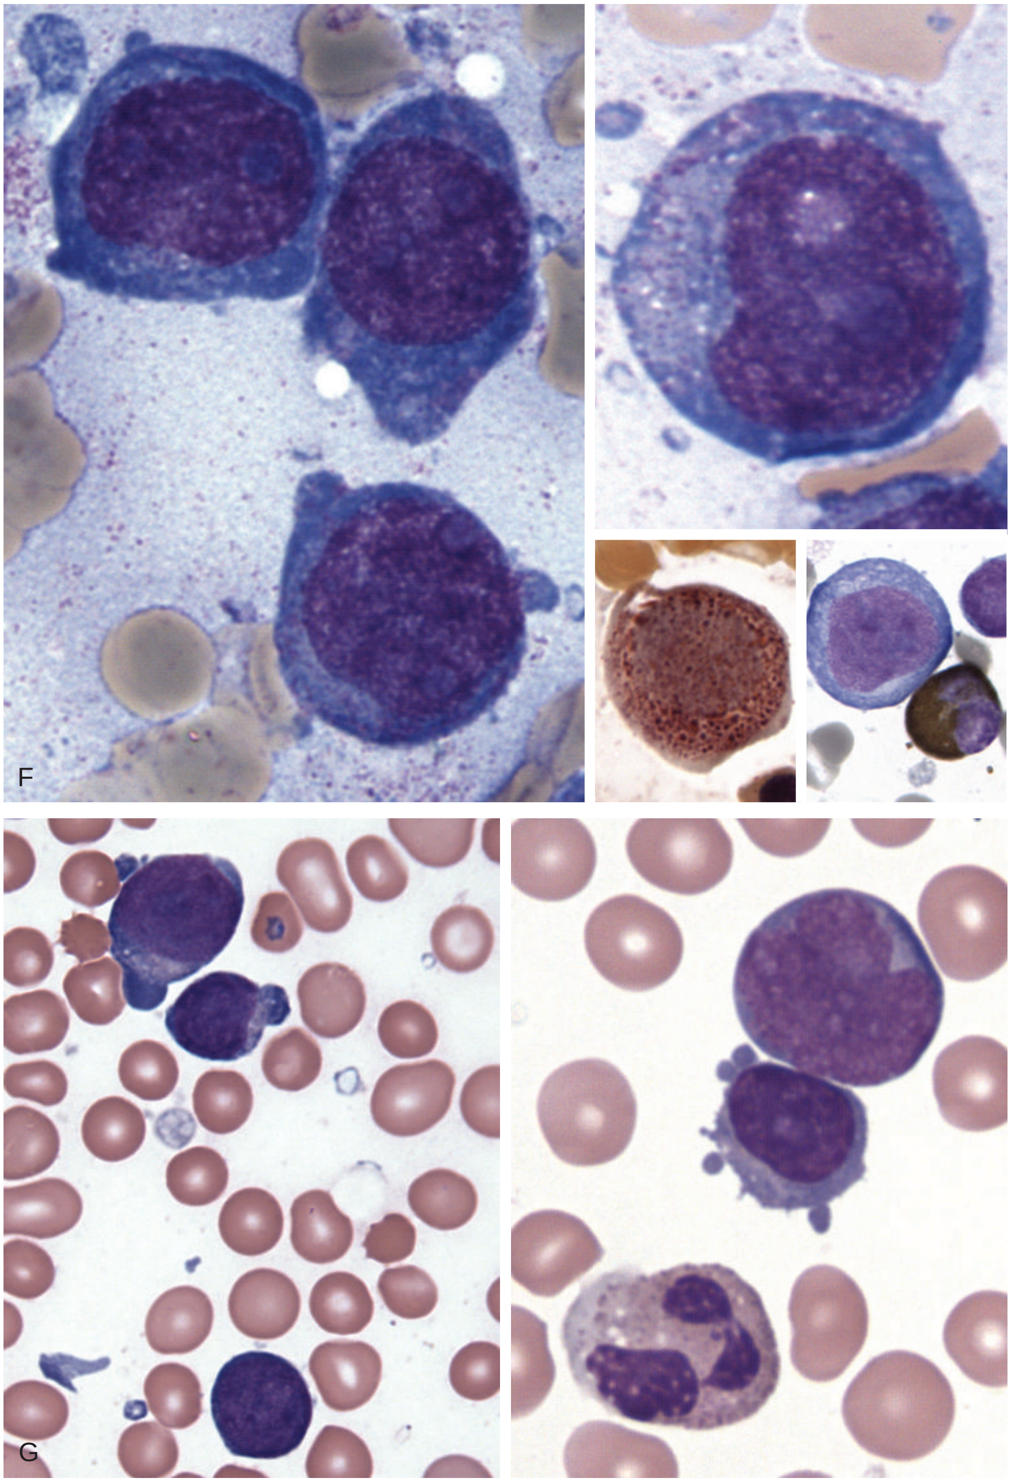

Figure 51-5, cont'd **F,** Acute monoblastic leukemia. Monoblasts are large and have round nuclei, prominent nucleoli, and abundant deeply basophilic cytoplasm, which may contain fine granules and/or vacuoles. Monoblasts show strong reactivity for nonspecific esterase *(lower right, left inset)* and are typically myeloperoxidase negative *(lower right, right inset)*. **G,** Acute megakaryoblastic leukemia. Megakaryoblasts are varied in size and have round, slightly indented or markedly irregular nuclear contours as well as fine chromatin, single to multiple small nucleoli, and scant to moderate basophilic (agranular or granular) cytoplasm, often with cytoplasmic blebs or pseudopod formation. *(Courtesy of Dr. Jo-Anne Vergilio, Assistant Professor in Pathology, Harvard Medical School.)*

AML, Acute myelogenous leukemia; *DS*, Down syndrome; *MLL*, mixed-lineage leukemia; *MPO*, myeloperoxidase; *NSE*, nonspecific esterase; *PAS*, periodic acid–Schiff; *SBB*, Sudan black B.

features (see Table 51-1). The system divides AML into seven subtypes, M1 through M7.[305,324,325] An M0 subtype was later added to describe undifferentiated leukemia and, since 1976, immunophenotypic data have also been included.[304,305,326] In general, AML can be differentiated from ALL based on morphologic features and cytochemical stains. Cells of myeloid origin should stain with myeloperoxidase and SBB. Cells of monocytic derivation usually stain with NSE. AML blasts usually do not have PAS activity, except for erythroblasts in AML-M6 and eosinophils of the M4Eo subtype.

M0: Acute Myeloblastic Leukemia with Minimal Differentiation. In patients with AML-M0, the bone marrow is usually hypercellular and more than 90% of the cells are blasts. Most blast cells lack cytoplasmic granules, nucleoli, or Auer rods, and results with MPO and SBB stains are negative.[304] Immunophenotypic analysis shows the presence of myeloid or monocytic cell antigens (i.e., CD13, CD14, CD33, or CD34) that are detectable on the cell surface of most AML-M0 blasts, but some AML-M0 blasts express terminal deoxynucleotidyl transferase, an enzyme usually associated with ALL. AML-M0 is associated with a high incidence of cytogenetic abnormalities, most of which are complex and often involve chromosomes 5 and 7, trisomy 8, or MLL rearrangements.[302,327]

M1: Acute Myeloblastic Leukemia without Maturation. The bone marrow of patients with AML-M1 is hypercellular and filled with myeloblasts (more than 90% blasts). Most blasts stain with MPO and SBB. The blast cells in this subtype display minimal myeloid differentiation. Morphologically, the blast cells may contain scant gray-blue cytoplasm and few or no azurophilic granules or Auer rods. Prominent nucleoli are usually detectable. Flow cytometric analysis usually shows that the blast cells of AML-M1 express HLA-DR, CD13, CD33, and CD34. Cytogenetic abnormalities for this subclass often include monosomy 5 or 7 or trisomy 8.

M2: Acute Myeloblastic Leukemia with Maturation. The bone marrow of patients with AML-M2 usually shows evidence of some maturation beyond the myeloblast, with evidence of maturation beyond the promyelocyte stage in more than 10% of nonerythroid cells. Myeloblasts must represent more than 30% of the bone marrow cells but less than 90% of nonerythroid cells. The blasts generally have a few clusters of primary granules and stain with MPO and SBB. Auer rods and prominent nucleoli are common. Immunophenotypic expression of HLA-DR, CD13, CD33, CD11, and CD15 is typical. This subtype may exhibit monosomy 5 or 7, trisomy 8, t(8;21), t(6;9), or abnormalities of chromosome 3.

M3: Acute Promyelocytic Leukemia. There are two types of AML-M3. The more common type is the hypergranular variant, in which more than 30% of the blasts are promyelocytes and myeloblasts. Most promyelocytes have heavy granulation. Auer rods and Auer rod bundles are common. In the rare microgranular variant, the cells exhibit fine cytoplasmic granules, which are not distinguishable by light microscopy and nuclear morphologic irregularities (i.e., microgranular M3 or M3v). The cells of both subtypes stain strongly with MPO and SBB and also with chloroacetate esterase. The promyelocytes usually do not show PAS and NSE activity. The blasts express CD13, CD33, CD11, and CD15, but they are HLA-DR– and CD14–. This subtype exclusively exhibits *RARA* rearrangements, the vast majority of which are t(15;17) leading to *PML-RARA*.

M4: Acute Myelomonocytic Leukemia. The M4 subtype is defined by the presence of blast cells with both granulocytic and monocytic features. The bone marrow in these patients has more than 30% infiltration by immature myeloid precursors, and there is often extramedullary involvement and a peripheral blood monocytosis. The blasts are usually pleomorphic with regard to size, amount of cytoplasm, granularity, and nuclear morphologic features. Some Auer rods can be seen, and prominent nucleoli are usually present. Staining is variable, with some of the blast cells showing positivity for MPO, SBB, and NSE. M4 AML may be associated with t(6;9), abnormalities of chromosome 3, and *MLL* gene rearrangements, in particular t(9;11). A small proportion of patients with AML-M4 have a moderate eosinophilia in their bone marrow (M4Eo). The eosinophils are notable for the presence of basophilic and eosinophilic granules and stain with chloroacetate esterase and PAS. Cell surface antigen expression includes CD13, CD15, CD33, CD4, CD11c, CD14, CD64, and HLA-DR. M4eo AML exhibits an inv(16) or t(16;16).

M5: Acute Monocytic Leukemia. More than 80% of the nonerythroid bone marrow cells in patients with AML-M5 are monocytic. There are two subtypes: M5a (undifferentiated) and M5b (differentiated). In AML-M5a, more than 80% of the cells are monoblasts. Patients with AML-M5a tend to be younger, have higher presenting white blood cell (WBC) counts, and have a poorer prognosis. In AML-M5b, fewer than 80% of the monocytic cells are monoblasts, and most of the cells are recognizable as monocytes or promonocytes. The peripheral blood in patients with AML-M5b exhibits a profound monocytosis. In both subtypes, the blasts demonstrate strong NSE activity. MPO and SBB staining results are usually negative. Cell surface antigen expression includes CD13, CD15, CD33, CD4, CD11c, CD14, CD64, and HLA-DR. M5 AML often exhibits *MLL* gene rearrangements, t(9;11) or t(11;17) in M5a and t(10;11) in M5b.

M6: Acute Erythrocytic Leukemia. AML-M6 is an uncommon form of AML overall and is rare in children. This form of leukemia is defined by a more than 50% erythroblast infiltration of the bone marrow. M6 AML may exhibit monosomy 5 or 7 or trisomy 8.

M7: Acute Megakaryoblastic Leukemia. The bone marrow exhibits an infiltration with pleomorphic megakaryoblasts that often display cytoplasmic budding and may appear in clusters. Aspiration of the bone marrow

may be challenging due to associated fibrosis. M7 blasts generally do not stain with MPO and SBB but show activity with PAS. Immunophenotyping is usually required to distinguish AML-M7 from ALL-L2, documenting the presence of the megakaryocytic antigens, glycoprotein Ib, glycoprotein IIb/IIIa, or factor VIII. Non–Down syndrome infants with M7 AML often exhibit a t(1;22). Down syndrome patients have a very high incidence of M7 AML with a particularly good prognosis, which is in contrast to the poor prognosis of M7 AML in non–Down syndrome children and adults.

World Health Organization Classification

The discovery of cytogenetic and molecular genetic abnormalities in malignant disease has had a significant impact on our understanding of malignant transformation. In myeloid malignancies, some genetic abnormalities have prognostic significance whereas others appear to define specific disease subtypes. The WHO has proposed a classification system for neoplastic diseases of the hematopoietic and lymphoid tissues that includes a classification for AML (see Box 51-2 and Fig. 51-5). This classification uses the traditional FAB-type morphologic categories of disease and includes additional entities such as immunophenotype, molecular genetic, and clinical characteristics that make the system more clinically relevant for diagnosis, prognosis, and treatment.[328] The WHO classification system divides myeloid diseases into several major subtypes—myeloproliferative neoplasms; myeloid neoplasm associated with eosinophilia and abnormalities of *PDGFRA*, *PDGFRB*, or *FGFR1*; myelodysplastic-myeloproliferative neoplasms; MDS, AML and related neoplasms; and acute leukemias of ambiguous lineage. The 2008 revision of the WHO classification has expanded the category of AML to include AML with recurrent cytogenetic translocations, AML with myelodysplasia-related changes, therapy-related myeloid neoplasms, AML not otherwise specified, myeloid sarcoma, myeloid proliferations related to Down syndrome, and blastic plasmacytoid dendritic cell neoplasms.[329]

Within the subtype containing recurrent cytogenetic translocations, seven additional categories have been described:

AML with t(8;21)(q22;q22); *AML1-ETO*; *RUNX1-RUNX1T1*
AML with inv(16)(p13.1q22) or t(16;16)(p13.1;q22); *CBFB-MYH11*
APL with t(15;17)(q22;q12); *PML-RARA*
AML with t(9;11)(p22;q23); *MLLT3-MLL*
AML with t(6;9)(p23;q34); *DEK-NUP214*
AML with inv(3)(q21q26.2) or t(3;3)(q21;q26.2); *RPN1-EVI1*
AML (megakaryoblastic) with t(1;22)(p13;q13); *RBM15-MKL1*

AML with t(6;9)(p23;q34) and AML with inv(3)(q21q26.2) is relatively uncommon in children. Myeloid sarcomas, formerly called chloromas, may precede hematopoietic evidence of disease and so are now classified as a separate entity. The myeloid diseases of Down syndrome were incorporated into the revised WHO classification in 2008 and are described later in this chapter. Plasmacytoid dendritic cell neoplasms were formerly referred to as blastic NK-cell lymphomas, but the nomenclature has changed to reflect the origin of this myeloid malignancy in this subset of dendritic cells. This rare disease can manifest in children with skin lesions, adenopathy, and ultimately bone marrow involvement. Blast cells characteristically express CD4, CD43, CD56, and CD123 without expression of CD34 or CD117.[329]

The FAB standard used to define AML had been 30% replacement of the bone marrow by the blast cells, but later studies have shown that patients with 20% to 30% blasts (previously classified as refractory anemia with excess blasts in transformation [RAEB-T]) have a prognosis similar to that of patients with more than 30% blasts. The blast count for the diagnosis of AML in the WHO classification was therefore changed to 20%, and the category of RAEB-T was eliminated.

Certain specific and recurrent cytogenetic abnormalities are common in MDS, in alkylating agent–related AML, and in de novo AML with a poor prognosis. These abnormalities include 3q–, –5, 5q–, –7, 7q–, +8, +9, 11q–, 12p–, –8, –19, 20q–, +21, t(1;7), t(2;11), and complex karyotypes. In the classification scheme, these cytogenetic abnormalities were considered to indicate a poor prognosis. Prior therapy with topoisomerase II inhibitors (i.e., epipodophyllotoxins and doxorubicin) was also associated with a poor prognosis. Typically, patients in whom AML develops after exposure to these agents have translocations involving 11q23 (*MLL*). The WHO classification includes these patients in the poor-prognosis category but distinguishes them from having alkylating agent–related secondary leukemia.

Patients may have MDS with unilineage or multilineage dysplasia, and these are reflected as distinct diseases in the most recent iteration of the WHO classification. Dysplasia is defined as being observed in greater than or equal to 10% of the cells of a given myeloid lineage. Children with 2% to 19% peripheral blasts or 5% to 19% bone marrow blasts can be classified according to the same criteria as adult MDS, but a new category of refractory cytopenia of childhood has been introduced to define children with persistent cytopenias and dysplasia of two or more lineages but less than 2% peripheral blasts or less than 5% bone marrow blasts.[329]

Clinical Presentation

The presenting signs and symptoms of AML result from leukemic blast cell infiltration of the bone marrow. The leukemia cells overwhelm the processes of normal hematopoiesis, resulting in anemia, thrombocytopenia, and neutropenia. It is rare for AML to be diagnosed incidentally on a routine medical evaluation, but there is considerable variability in the range of presenting signs and symptoms in patients with de novo AML. Usually, patients seek medical attention for fever, fatigue, pallor, skin or mucosal bleeding, bone pain, or infections not responding to appropriate antibiotic therapy.[330] Bone pain is a common symptom, and patients may present with a limp, rib pain, or back pain.[330]

The WBC count of patients with newly diagnosed AML can range from less than 1,000/μL to more than 500,000/μL.[330-332] The leukocyte count is more than 100,000/μL in approximately 25% of pediatric patients with AML, and an elevated count is more common in those with the M4 and M5 subtypes and in those with *FLT3*-ITD mutations.[174,175,330,333,334] The number of circulating granulocytes is often critically decreased, regardless of the total leukocyte count, and, because their function is usually impaired, the risk for overwhelming bacterial infection in patients with newly diagnosed AML is markedly increased. Patients with AML who have a fever require immediate treatment with broad-spectrum antibiotics after appropriate culture samples have been obtained. The hemoglobin level is occasionally normal but is usually less than 9 g/dL, and levels as low as 3 g/dL at diagnosis are not uncommon. About half of children with new-onset AML have platelet counts of 50,000/μL or less, which increases the risk for life-threatening bleeding.[330]

Disseminated intravascular coagulation (DIC) has been observed in patients with all FAB subtypes of AML but is most common in acute promyelocytic leukemia (APL; see later). Before the development of ATRA, treatment with low-dose heparin during induction was initiated for patients with AML-M3 to prevent DIC.[335,336] The later addition of ATRA to induction therapy rapidly resolved DIC in patients with AML-M3 and markedly reduced early mortality.[191,337-340]

Patients with hyperleukocytosis have an increased risk for mortality from leukostasis, particularly in the brain or lung, and urgent leukapheresis or treatment with leukocyte-reducing agents such as hydroxyurea may be necessary (see “Complications”).[341,342] Extramedullary leukemia occurs in 20% to 25% of children with AML and may include chloromas (tumor nodules), skin infiltration, CNS disease, gingival infiltration, hepatosplenomegaly, or testicular involvement.[330,343] Chloromas (e.g., myeloblastomas and granulocytic sarcomas) are solid tumors of myeloblasts that may occur in any area of the body but are most common in the orbit and epidural area.[344] Skin infiltration, or leukemia cutis, usually presents as slightly purple lesions (i.e., “blueberry muffin” spots), is more common in infants with monocytic leukemia, and may be the initial sign of disease.[345] CNS involvement at diagnosis is more common in AML than in ALL. Up to 15% of patients with AML have myeloblasts in the cerebrospinal fluid at diagnosis.[346-349] Gingival infiltration may present as hyperplasia, often accompanied by bleeding.[350] Severe extramedullary disease with massive hepatosplenomegaly is also a more common finding in infants.[345] Extramedullary involvement of the testes can also be documented but is less common than in ALL.[351,352] Extramedullary infiltration, particularly gingival involvement, is more common with the M4 and M5 (acute myelomonocytic and acute monoblastic and monocytic) leukemias.[350,353,354] Chloromas and CNS disease are more common in AMLs with t(8;21). Extramedullary infiltration in pediatric patients is not clearly associated with worse prognosis unless accompanied by a high presenting WBC count.

Treatment

As is true for any pediatric cancer, the goal of therapy for children with AML is to completely eradicate the disease while limiting treatment-induced toxicity. In general, therapy for AML includes immediate supportive care measures followed by intensive remission induction and consolidation chemotherapy. At any given time, several large, multicenter phase III clinical trials are ongoing, each aimed to improve overall survival (OS) through randomized comparisons of treatment options while minimizing short- and long-term toxicities.

Remission Induction

During the past 40 years, survival rates for patients with AML have risen from less than 10% to more than 50% of patients because of intensification of chemotherapy, use of hematopoietic stem cell transplantation (HSCT), and improved supportive care. The first phase of chemotherapy is termed *induction* and consists of two to four cycles of intensive chemotherapy with the goal of inducing remission. Morphologic remission is defined as the presence of fewer than 5% blasts visible on bone marrow aspirate obtained after recovery of counts. Patients may also achieve cytogenetic and FISH-negative remission, as defined by the absence of a previously detected leukemic clone–associated cytogenetic abnormality in the bone marrow cells. Remission is also now being defined by the absence of MRD, assessed by multiparameter flow cytometry that is designed to detect as few as 0.1% leukemic blasts in the marrow. The inclusion of MRD evaluation has not only identified children at risk for relapse who appeared to be in morphologic remission but has also revealed false-positive recovering marrows that had been deemed refractory disease.[355]

Induction chemotherapy should be initiated as soon as the diagnosis of AML is confirmed, preferably by morphologic, immunophenotypic, and cytogenetic studies of the bone marrow. In some cases, particularly in patients presenting with hyperleukocytosis, the patient's condition may be too unstable for bone marrow evaluation, in which case the diagnosis can often be confirmed on studies of the peripheral blood. Induction chemotherapy regimens consist of high-dose myelosuppressive cytotoxic agents that result in prolonged pancytopenia. The period of bone marrow hypoplasia generally lasts from 21 to 30 days from the initiation of therapy but may last considerably longer. During this period, patients have a high risk for life-threatening infection and bleeding. Aggressive supportive care is necessary (see later).

Historical North American Approaches to Treating AML. The basis of modern induction therapy for AML is a combination of cytarabine and an anthracycline. The classic combination therapy was the so-called 7 + 3 regimen, which consists of a continuous 7-day intravenous infusion of cytarabine at 100 to 200 mg/m^2/day and 3 days of bolus infusions of daunorubicin at 45 to 60 mg/m^2/day. Remission is achieved in 60% to 70% of patients with newly diagnosed AML using this regimen.[356-358] In children, several strategies have been used to intensify this regimen to achieve higher rates of CR. CCG trial 213 added etoposide, thioguanine, and dexamethasone to the traditional 7 + 3 regimen to create the five-drug Denver regimen. The Denver and 7 + 3 regimens were compared in a randomized fashion, and there was no significant difference in CR rate, with 79% of children achieving CR with 7 + 3 and 76% achieving CR with Denver regimen.[359]

In CCG trial 2891, the same drugs were used but the timing was intensified in an attempt to improve CR. The hypothesis was that leukemia cells may be recruited synchronously into the cell cycle after chemotherapy, and therefore reexposure at an earlier time point may affect cells while more of them are at a sensitive phase in the cell cycle. Thus the Denver regimen was modified into the five-drug DCTER regimen, again consisting of ***d***examethasone, ***c***ytarabine, ***t***hioguanine, ***e***toposide, and ***R***ubidomycin (daunorubicin). Induction consisted of a total of four cycles of chemotherapy, and patients were randomized to standard or intensive timing. For standard timing, each cycle of induction began with count recovery from the previous cycle. With intensive timing, cycles 2 and 4 began at day 10 after the start of cycles 1 or 3, respectively, regardless of hematologic status. Not surprisingly, the intensive timing resulted in far greater toxicity, with 11% of patients in this arm of the trial dying of toxicity compared with only 4% of patients dying of toxicity in the standard timing trial arm.[360] Because of this, better supportive care measures were instituted for the intensive timing trial arm, including more aggressive empiric antibiotic and antifungal coverage and the use of granulocyte colony-stimulating factor (G-CSF). Interestingly, the CR rates were similar for the two arms in the trial—75% for intensive timing and 70% for standard timing—but the reason for failure to achieve remission was different, with 11% toxic death and only 14% resistant disease in the intensive timing arm versus only 4% toxic death but 26% resistant disease in the standard timing arm. The most dramatic results, however, came later, when it was shown that for patients who achieved a CR there was a 3-year disease-free survival (DFS) of 55% for those who had been treated in the intensive timing arm, versus a DFS of only 37% for patients who had received standard timing. For this reason, the standard timing arm of the trial was closed early and an intensive timing DCTER/DCTER schedule became the new standard combination therapy for newly diagnosed AML patients.

In the meantime, a comprehensive review of five randomized trials comparing idarubicin with daunorubicin as induction therapy for AML had shown improved remission induction rates and OS for patients receiving idarubicin.[361] For this reason, the CCG pilot trial 2941 tried to intensify therapy further by using idarubicin in place of daunorubicin in each cycle of the intensively timed regimen. Because of unacceptably high toxicity, with a toxic death rate of 14%, this was modified to idarubicin only in cycles 1 and 3, and more strict supportive care guidelines were put into place, including mandatory hospitalization during neutropenia, and stricter infection prophylaxis (see later, "Supportive Therapy at Diagnosis and during Therapy").[362] The addition of idarubicin showed no advantage in remission induction or event-free survival (EFS) but did show a decrease in marrow blasts at day 14 of induction. CCG trial 2961 continued to use the hybrid idaDCTER/DCTER intensive timing induction regimen resulting in induction remission rates of 89%, which were similar to historic controls. Most of the improvement was believed to be related to better supportive care rather than to the change in chemotherapy.

Medical Research Council Trials (MRC10, MRC12, and MRC15). During this period, data emerged from the British MRC trials that seemed to show better survival and less toxicity. MRC10 induction chemotherapy randomized DAT (daunorubicin, cytarabine, thioguanine) to ADE (cytarabine, daunorubicin, etoposide) in a 10-day cycle of chemotherapy followed by an 8-day cycle of the same drugs on WBC count recovery. The CR rate for children in this study was 93%, with a 4% rate of toxic death and a 3% rate of resistant disease.[363] Early data suggested a benefit for pediatric patients using ADE versus DAT, but the later data showed no difference in 10-year OS (DAT, 57%; ADE, 51%; $P = .3$), DFS (DAT, 53%; ADE, 48%; $P = .3$) or EFS (DAT, 48%; ADE, 45%; $P = .5$).[363,364] Because of the early results possibly favoring ADE, MRC12 compared ADE with MAE (mitoxantrone, cytarabine, etoposide) in a 10-day cycle followed by an 8-day cycle on count recovery. The CR rates were similar for the two groups (ADE, 92%; MAE, 90%; $P = .3$) with a slight increase in toxic deaths for the MAE group (ADE, 3%; MAE, 6%) but a lower relapse rate (ADE, 39%; MAE, 32%) and better DFS rate for the MAE group (ADE, 55%; MAE, 63%), although the 10-year EFS and OS rates were not significantly different (54% and 63%, respectively).[363,365] In MRC15 there were three randomized induction backbones—ADE; cytarabine and daunorubicin without etoposide, or idarubicin, fludarabine, cytarabine, and G-CSF (Ida-FLAG)—and three randomized consolidation backbones—amsacrine, cytarabine, and etoposide; cytarabine 1.5 g/m^2; or cytarabine 3 g/m^2 with and without the addition of gemtuzumab ozogamicin (GMTZ, GO, Mylotarg).[371] GMTZ, a recombinant humanized anti-CD33 monoclonal agent linked to the tumor antibiotic calicheamicin, was incorporated as a targeted therapy in these studies. Because CD33 is expressed on most AML cells but not on pluripotent HSCs or other tissues, this drug can target leukemia cells more specifically.[367,368] GMTZ was well tolerated overall, but no overall improvements in survival or relapse rate were observed regardless of the chemotherapy backbone in either induction or consolidation.[371]

Recent U.S. Trials. The next series of U.S. trials built on the data from these recent MRC studies. The COG has undertaken three therapeutic trials to date based on an MRC backbone. The COG AAML03P1 pilot and AAML0531 phase III groupwide study backbone included cytarabine/daunorubicin/etoposide (ADE 10+3+5) followed by ADE 8+3+5, cytarabine/etoposide (AE), mitoxantrone/cytarabine (MA), and, finally, high-dose cytarabine (Capizzi II) for children who did not go on to receive HSCT. The COG pilot trial AAML03P1 assessed the safety of adding a single dose of GMTZ to ADE 10+3+5 and MA cycles. Toxicity on this pilot study was acceptable, so GMTZ was added to these same two cycles on AAML0531 in a 1:1 randomization. Subsequent outcome data from the AAML03P1 trial demonstrated a 3-year EFS of 53% and OS of 66% with no increased treatment-related mortality over backbone chemotherapy.[369] Outcome data have not yet been released for AAML0531. However, after data were released from the Southwest Oncology Group (SWOG) Study 106, the U.S. Food and Drug Administration (FDA) removed GMTZ from the U.S. market because this adult-based study showed no benefit in outcome to the addition of GMTZ but an increase in induction deaths.[370] By contrast, subgroup analysis on the MRC 15 trial found that the addition of GMTZ to induction chemotherapy was of benefit to CBF AML and to intermediate-risk patients and did not contribute to increased toxicity.[371] Data from the COG AAML0531 trial demonstrated mixed results. GMTZ improved 3 year EFS and relapse risk for all patients but not OS. Interestingly, positive trends were seen for GMTZ in subgroup analysis, including OS in high risk patients and relapse risk in low risk patients, although this was also associated with increased TRM in the low risk subgroup.[371a] Given this controversy regarding both toxicity and efficacy and the absence of data from the AAML0531 at the time of study initiation, GMTZ was not included on the current COG AAML1031 trial. However, other co-operative groups are planning future trials to examine the optimal dosing of GMTZ in pediatric AML (A. Gamis, personal communication, July 2014). The current COG trial risk stratifies patients into high- and low-risk AML based on cytogenetics and MRD and randomizes the addition of the proteosome inhibitor bortezomib as a potential AML stem cell targeted therapy. In addition, patients harboring the *FLT3*-ITD with sufficient allelic ratio have the option of being nonrandomly assigned to an MRC-based backbone arm with the addition of the FLT3 inhibitor sorafenib. Given recent MRC data that four cycles appear as effective as five cycles of therapy,[365] only four cycles are included on this protocol (ADE 10+3+5; ADE 8+3+5; cytarabine and etoposide; and mitoxantrone and cytarabine) for good responders. Patients with positive MRD after cycle 1, defined as more than 0.1% by multiparameter flow cytometry (MPFC) receive mitoxantrone and cytarabine instead of an additional ADE cycle, and high-risk patients receive high-dose cytarabine for cycle 4.

The St. Jude Children's Research Hospital (SJCRH) trial AML02 randomized patients to standard low- or high-dose cytarabine during the first cycle of induction together with etoposide and daunorubicin (ADE), although this was not found to impact remission rate, EFS, or OS.[372] Toxicity was generally similar in both arms of the trial, although patients treated on the high-dose arm had a greater incidence of serious fungal infections. The SJCRH trial incorporated MRD measurements during induction to guide therapy. MRD by MPFC was determined on a bone marrow sample obtained on day 22 of induction. Patients with MRD greater than 1% on day 22 received induction II before WBC count recovery. Patients with MRD greater than 1% at the end of the first month of induction I received GMTZ in addition to the second cycle of ADE. Patients with CNS-positive disease received triple intrathecal therapy. Patients who were MRD positive after induction I had a significantly worse outcome than patients who were MRD negative (3-year EFS, 43% vs. 74%). However, subgroup analysis revealed that this difference was only found in patients with high-risk AML at diagnosis (*FLT3*-ITD positive, monosomy 7, t(6;9), megakaryoblastic leukemia, therapy-related AML, or AML after MDS) or those with MRD levels greater than 1%. Low- and standard-risk AML patients or those with what was referred to in this study as low-level MRD (0.1% to 1%) did not demonstrate any outcome differences versus those with negative MRD. However, 20 patients who were MRD negative ultimately experienced relapse.[372] In the current SJCRH study, AML08, patients are randomly assigned to receive high-dose cytarabine, etoposide, and daunorubicin versus clofarabine and cytarabine in induction I. Low-risk patients (those with CBF leukemia with negative MRD after induction I) receive 4 courses of chemotherapy, whereas those at high risk for relapse—*FLT3*-ITD positive, monosomy 7, t(6;9), t(8;16), t(16;21), megakaryoblastic leukemia without t(1;22), treatment-related AML, AML after MDS, or MRD greater than 0.1% after induction II—receive two to three courses of chemotherapy followed by allogeneic HSCT. Standard-risk patients receive four courses of chemotherapy and are then eligible to receive one course of natural killer cell therapy if they have a killer cell immunoglobulin-like receptor (KIR)-mismatched haploidentical family member. Patients with *FLT3*-ITD receive sorafenib after each course of chemotherapy (J. Rubnitz, personal communication).

The BFM (Berlin-Frankfurt-Münster) trial for de novo AML, BFM-2010, is for all comers, including patients with APL. Patients are being randomized to ADE ± GMTZ in induction I with MRD measurements on day 8, 15 and 28. Induction II includes cytarabine and idarubicin (AI) for patients with inv(16) and APL (who also receive ATRA). Other favorable-risk patients, including those with t(8;21), *NPM1* mutations, and *CEBPA*, receive HAM (high-dose cytarabine 3 g/m^2 and mitoxantrone), and high-risk patients receive HAM plus targeted therapy, such as sorafenib if *FLT3*-ITD positive, or dasatinib if *KIT* mutant positive. The third course is hAM (high-dose cytarabine at 1 g/m^2) for those who received AI and AI for low-risk patients who received HAM, with AI plus cladribine for the high-risk patients. Course 4 is hAM, except for the inv(16) and APL patients who receive cytarabine or cytarabine and etoposide as a final cycle. For all other patients, course 5 is high-dose cytarabine and etoposide. Liposomal daunorubicin, available in Europe, will be used in this trial. Prior studies have shown it to have equal efficacy in induction to idarubicin with less toxicity[373,374] (G. Kaspars, D. Reinhardt, and D. Johnston, personal communication, January 2013).

Postremission Therapy

Several randomized studies have demonstrated that without postremission therapy almost all patients with newly diagnosed AML suffer a relapse within 2 years.[375-377] The strategies for postremission therapy include autologous HSCT, allogeneic HSCT, or continued courses of chemotherapy. The CCG trials have shown no benefit to autologous HSCT over continued cycles of chemotherapy so, although that strategy continues to be used in some European trials, autologous HSCT is not included in current U.S. trials.[364,378-384] Most studies have shown a lower relapse rate for AML patients treated with matched related donor HSCT versus chemotherapy, but the OS is often no better because of the significant morbidity and mortality of HSCT.[381,383-396] For this reason, until the most recent trials, unrelated donor HSCT was believed to be too morbid for patients in first remission and thus trials used a genetic randomization, wherein all patients with a matched related donor proceeded to HSCT and all others proceeded with further cycles of chemotherapy.[383,385,386]

Based on the success of the MRC trials with chemotherapy alone using a combination of cytogenetic characteristics and response to therapy,[363,364,386,397] the COG and SJCRH adopted risk-based criteria for HSCT. HSCT, even from a matched related donor, is not recommended for patients with low-risk disease. This was previously defined by COG as the presence of t(8;21) or inv(16) in the leukemic clone at diagnosis, but more recently the presence of a *CEBPA* or *NPM1* mutation has been added to this definition, based on the data revealing the better outcome for these patients.[279,398] The COG has classified high-risk disease as monosomy 7, −5/5q−, *FLT3*-ITD with high allelic ratio, MRD positive after induction chemotherapy, or more than 15% blasts in the marrow after one course of induction chemotherapy.* The incorporation of MRD after induction has enabled the COG to relegate normal karyotype patients to high- and low-risk groups, thereby dichotomizing patients and eliminating the intermediate-risk category. Therefore on the current AAML1031 protocol, high-risk patients will receive best available donor HSCT for consolidation, whereas good-risk patients will not go to transplant even if a sibling donor match is available. With recent advances in supportive care and improved therapy to prevent and treat graft-versus-host disease (GVHD), outcomes have improved for matched related and matched unrelated donor HSCT.[381,390,391,393] Therefore for patients with high-risk disease, both trials recommend HSCT in first CR with an unrelated donor if no matched family donor is identified. The optimal number of cycles of chemotherapy before HSCT to balance minimizing toxicity while minimizing MRD is variable, with the MRC10 trial using four cycles, the current SJCRH trial including two to three cycles, and the COG trial using three cycles before HSCT.[363,364]

For patients who do not proceed to HSCT there is controversy as to how many courses of chemotherapy are needed and what chemotherapy should be included. Several trials have shown that cycles of high-dose cytarabine after remission are associated with improved long-term survival.† MRC12 randomized patients to receive four versus five total cycles of chemotherapy, with early results suggesting that five cycles are superior; thus that strategy was subsequently used in the current U.S. trials.[397] However, more recent data from the MRC have shown that the fifth cycle added toxicity with no additional therapeutic benefit.[411] These findings are reflected in the current COG trial in which only four cycles of chemotherapy are used for good-risk patients with elimination of the high-dose cytarabine and asparaginase cycle (Capizzi II) that previously comprised the fifth cycle on AAML0531 and AAML03P1.[409,410,412,413] High-risk patients for whom a donor is not identified also only receive four cycles of chemotherapy, but they do receive Capizzi II as their last consolidation cycle. The SJCRH trial has tried to make up for the lack of amsacrine by tailoring the first postinduction cycle based on the patient's AML subtype and cytogenetics. On AML02, patients with t(9;11) or inv(16) AML receive cytarabine and cladribine, patients with M4/M5 AML receive cytarabine and etoposide, and patients with t(8;21) and all others receive high-dose cytarabine

and mitoxantrone[311,414-419] followed by two courses consisting of cytarabine and asparaginase followed by cytarabine and mitoxantrone.[409,410,412,413] However, based on small subgroup numbers, AML08 uses a single backbone for all patients with the addition of sorafenib for patients with *FLT3*-ITD (J. Rubnitz, personal communication, January 2013). CNS leukemia in patients with AML is highly sensitive to chemotherapy, and the addition of cranial irradiation does not decrease CNS relapse compared with systemic and intrathecal chemotherapy. Therefore, cranial irradiation is no longer part of the therapy for patients with AML.[420] However, CNS-positive patients defined on the current COG AML study as having even one blast in the cerebrospinal fluid are treated with additional intrathecal cytarabine until the fluid is clear of blasts and for two additional intrathecal treatments beyond. Furthermore, in pediatrics, the addition of prolonged low-intensity maintenance therapy is associated with lower OS because of more resistant disease at relapse, so maintenance therapy is not used in the current U.S. trials.[421-423]

Supportive Therapy at Diagnosis and during Therapy

The diagnosis and treatment of childhood AML require a multidisciplinary approach involving pediatric oncologists, hematopathologists, pediatric surgeons, infectious disease specialists, pediatric intensivists, and pediatric nurses. While studies and procedures are initiated to make the diagnosis, special care must be taken to prevent and treat the life-threatening consequences of leukemia and accompanying pancytopenia. The most serious complications of leukemia at diagnosis are infection and bleeding with pancytopenia, tumor lysis syndrome, and leukostasis. The most common causes of death once remission is achieved are relapse, infection, hemorrhage, and cardiac events.[385,424] The improvement in OS of patients with AML over the past several decades is attributable as much to better supportive care efforts as to more effective treatment regimens.[425]

Infectious Complications. At the time of initial presentation, up to 40% of patients with leukemia exhibit fever, and most of these patients are neutropenic or have impaired neutrophil function.[330] During remission induction and subsequent cycles of chemotherapy, all AML patients experience profound prolonged neutropenia and are at high risk for life-threatening bacterial infections, particularly viridans group streptococcal infections.[424,426-428] Almost all AML patients experience at least one febrile neutropenic episode during therapy, and approximately 40% of these patients will have a documented infection; most commonly these are bacterial infections, followed by viral infections and then fungal infections. Infections account for nearly two thirds of deaths in patients in remission.[385,424,428] Therefore supportive care during induction and postremission therapy must pay particular attention to prophylactic, empiric, and treatment coverage for infectious complications. Several strategies are used to prevent infection or decrease mortality from infection. Some centers isolate patients receiving AML therapy in laminar airflow rooms during episodes of neutropenia.[424,429] The supportive care guidelines for the CCG 2961 study included mandatory hospitalization for all patients, whether febrile or not, until the absolute phagocyte count had risen, and this rule has been strongly recommended in current COG trials. On CCG 2961, almost 50% of patients developed gram-positive infections and approximately 25% developed gram-negative infections across all phases of therapy. Infection-related mortality was 11%, including death from fungus. Bacterial agents included coagulase-negative staphylococci and α-hemolytic streptococci (including viridans streptococci) as well as *Klebsiella* and *Pseudomonas* species.[430] To decrease the rate of bacterial infections, some programs routinely prescribe the use of gut decontamination, mouthwashes, or prophylactic antibiotics.[385,425] A study by SJCRH demonstrated that initiation of antibiotics at the onset of neutropenia prevented sepsis, with the optimal regimen including both vancomycin and ciprofloxacin.[431] This remains an area of controversy because, in some studies, although prophylaxis may decrease the rate of bacterial infection it may also be associated with an increase in drug-resistant organisms. Further investigation is indicated in a prospective randomized fashion before it is widely adopted.[424,429,432-438] For example, in the SJCRH study, an earlier regimen of vancomycin and cefepime resulted in two cases of life-threatening resistant gram-negative bacteria and one of *Bacillus cereus*, leading to the change to ciprofloxacin for gram-negative coverage.[431] The COG is currently conducting a study of a related fluoroquinolone, levofloxacin, for bacterial prophylaxis in AML and patients with relapsed ALL. Patients will be randomized to receive levofloxacin versus no bacterial prophylaxis from the initiation of chemotherapy for two consecutive cycles. In contrast to the controversy regarding bacterial prophylaxis, there is broad agreement that patients who are febrile at initial presentation and patients who experience febrile neutropenia during therapy should be immediately started empirically on broad-spectrum antibiotics, including vancomycin, once cultures have been obtained.[439-441] In many centers, vancomycin is discontinued after 48 to 72 hours if there is no evidence of gram-positive bacteremia.[424] Typhlitis, or generalized bacterial infection of the cecum, is more common in children than in adults and is more common in patients treated with doxorubicin instead of daunorubicin.[442,443] Although this is a potentially life-threatening complication, conservative management with broad-spectrum antibiotics and nothing by mouth is generally preferable to surgical treatment in the setting of profound neutropenia.[444]

AML patients are at high risk for invasive fungal infection, which carries a high risk for mortality. The routine use of fungal prophylaxis is becoming more routine given the intensity of AML protocols. Data from the CCG 2961 study demonstrated *Candida* and *Aspergillus* infections in approximately 13% of patients across all phases of therapy and a strong association with infection-related mortality.[430] Some early studies have shown a decrease in some *Candida* species with fluconazole prophylaxis, but an increase in *Candida krusei* infections was documented, with no decrease in infection by invasive molds.[445-447] Two meta-analyses have concluded that there is a reduction in morbidity because of invasive fungal infections when prophylaxis is used for those with prolonged neutropenia and post-HSCT patients.[448,449] A randomized controlled trial of posaconazole versus fluconazole or itraconazole as fungal prophylaxis in neutropenic patients with AML or MDS has shown a lower rate of invasive fungal infections and improved OS in the posaconazole group.[450] However, posaconazole has not been studied in children younger than age 13 years and, owing to exclusively oral administration, may have limitations during administration of emetogenic AML chemotherapy. Voriconazole has been studied as a prophylactic agent that has activity against both yeast and aspergillus, but the incidence of invasive fungal infections was no different compared with fluconazole or itraconazole.[451-453] Voriconazole, similar to posaconazole, is metabolized through hepatic CYP450, leading to numerous interactions with other drugs and contributing further to a lack of enthusiasm in using either of these agents prophylactically. Thus fluconazole remains the most frequently used agent for fungal prophylaxis but lacks activity against *Aspergillus*.[451,454] Currently the COG is conducting a study randomizing patients with AML to caspofungin versus fluconazole for fungal prophylaxis. Caspofungin is from the echinocandin family of antifungal agents that functions by targeting fungal cell wall biosynthesis of β-1,3-glucan. It is effective against both *Candida* and *Aspergillus* species and has safety data in children as young as 3 months of age.[455-457] Caspofungin is given intravenously and is generally well tolerated but has minimal CNS penetration.

A test to detect galactomannan-containing *Aspergillus* antigens in the sera of immunocompromised patients has become commercially available. At this point, the galactomannan assay has been used most advantageously to follow the status of invasive aspergillosis and its response to therapy.[458,459] However, some centers do not use fungal prophylaxis during AML therapy but rather screen twice weekly with the galactomannan assay and use a low threshold for computed tomography (CT) to detect early invasive disease.[460,461] Whether or not fungal prophylaxis is used, empirical fungal therapy should be initiated for neutropenic patients who remain febrile for longer than 5 days, although some centers use a threshold of 72 hours. Patients who need empiric fungal therapy should be routinely scanned during neutropenia and after the recovery of circulating neutrophils be screened for evidence of fungal disease, and the diagnosis of fungal infection should be made by biopsy whenever feasible. Amphotericin has long been the antifungal agent of choice for empiric therapy, and the liposomal forms appear to be equivalent in efficacy and less toxic to renal function.[462,463] One prospective randomized trial has shown that caspofungin as empiric fungal therapy is as effective as liposomal amphotericin B and is generally better tolerated.[464] Whereas caspofungin is well tolerated with few drug interactions, as mentioned earlier, it does not cross the blood-brain barrier and thus is ineffective at treating suspected or proven CNS fungal infections. Voriconazole as empiric fungal therapy was compared with amphotericin in a prospective randomized trial and found to provide comparable coverage with less renal toxicity but with more visual changes and hallucinations.[465] Voriconazole is seldom used empirically unless *Aspergillus* is highly suspected, such as in the case of prolonged febrile neutropenia with pulmonary lesions on imaging.

All patients undergoing AML therapy should receive prophylaxis against *Pneumocystis carinii* (now called *P. jirovecii*) pneumonia (PCP). The first-line agent in PCP prophylaxis is trimethoprim-sulfamethoxazole, but in some patients this is associated with significant allergic reaction or prolonged bone marrow suppression.[466-468] Dapsone is also effective as PCP prophylaxis in pediatric oncology patients but is associated with significant hemolysis and methemoglobinemia in some patients.[469] Atovaquone has been shown to be highly effective as PCP prophylaxis for pediatric leukemia patients, although it may be associated with gastrointestinal side effects, including pancreatitis.[470] Aerosolized pentamidine has also been shown to be effective as PCP prophylaxis in children with leukemia, although it may be associated with significant bronchospasm and can only be administered to children old enough to comply with the inhalational administration (usually >5 years).[471]

Viral infections can be a significant cause of morbidity and mortality in AML patients as well. CCG 2961 and COG AAML0531 advocate intravenous immune serum globulin (IVIG) administration for low IgG levels, and some centers also recommend respiratory syncytial virus (RSV) prophylaxis for infants. All blood products transfused should be leukoreduced and cytomegalovirus (CMV) negative whenever possible. Acyclovir may be required for patients with recurrent zoster or mucocutaneous herpes simplex.[472]

Growth factors, such as G-CSF and granulocyte-macrophage colony-stimulating factor (GM-CSF), have been used in the past, both as priming agents to synchronize the cell cycle before chemotherapy and as supportive care to decrease the duration of neutropenia after chemotherapy. Trials have shown that although G-CSF does shorten the duration of neutropenia its use does not lead to fewer episodes of febrile neutropenia, fewer microbiologically documented infections, less infection-related mortality, or improved OS.[425,473-476] Based on these data, most centers no longer advocate the routine use of growth factors as supportive care during AML therapy.

Bleeding Complications. Severe thrombocytopenia is not unusual in leukemia patients, and hemorrhage is one of the leading causes of early mortality in these patients.[477-479] AML patients who present with bleeding and thrombocytopenia should be treated with platelet transfusions. In patients who are thrombocytopenic but do not have active bleeding, concern still remains about spontaneous bleeding, particularly intracranial bleeding, which can be catastrophic and have irreversible sequelae. The level of thrombocytopenia that warrants prophylactic platelet transfusion to prevent bleeding, however, is controversial. Some early observations suggested that platelet counts less than 20,000/μL predispose to increased bleeding, and that number became a standard threshold for transfusion.[480] However, this was primarily in patients also receiving aspirin therapy, and subsequent studies have shown spontaneous bleeding occurs at a similar rate with platelet counts of less than 10,000 or 20,000/μL; and many centers have adopted 10,000/μL as the new threshold for transfusion.[481-487] The threshold for platelet transfusion in patients undergoing procedures such as line placement or lumbar puncture has also not been well studied, and the accepted standard threshold of 50,000/μL may be higher than necessary.[480,488] All blood products should be leukoreduced or CMV negative to prevent CMV infection, and irradiated to prevent transfusion-related GVHD.[489-491] Menstruating women may require hormonal menstrual suppression for the duration of therapy with expected platelet drops to less than 50,000/μL.

Patients with AML, particularly APL, may also present with DIC, and coagulation studies should be a routine part of the initial workup in a patient with AML.[492,493] In APL, overexpression of one of the plasminogen receptors, annexin A2, has traditionally been implicated as the cause of increased production of the fibrinolytic protein plasmin, which may be part of the cause of DIC in these patients.[494] However, recent in vitro studies performed in APL cell lines suggest that, in fact, a different plasminogen receptor, S100A10 (also known as p11), may actually be the culprit. Levels of S100A10 increased concomitantly with *PML-RARA* induction, and targeted inhibition of SA100A10 expression resulted in decreased fibrinolytic activity.[495] Patients whose leukemic cells are successfully treated will exhibit resolution of DIC with the reduction in blast cells but, while the blast count is decreasing, DIC should be treated with fresh-frozen plasma, cryoprecipitate, or recombinant factor VIIa as needed to prevent bleeding. For patients with APL, the initiation of ATRA before chemotherapy leads to rapid resolution of DIC and has markedly reduced the early mortality previously associated with APL.[338-340,496] Since the development of ATRA, patients with APL are no longer routinely treated with low-dose heparin to prevent DIC.[335,336]

Complications of Hyperleukocytosis. Patients with AML, particularly those with high presenting leukocyte counts, have an increased risk for tumor lysis syndrome. In patients with leukemia, the rate of blast cell turnover can exceed the body's ability to metabolize and excrete the contents of dying cells, leading to life-threatening metabolic derangements.[497] Hyperuricemia resulting from the metabolism of excessive amounts of released nucleic acids can cause renal failure. The ensuing hyperkalemia may lead to fatal cardiac arrhythmias, and hyperphosphatemia and hypocalcemia may cause seizures and worsen the renal failure. Elevated blood urea nitrogen levels cause platelet dysfunction, which may exacerbate an existing coagulopathy. Vigorous intravenous hydration and administration of bicarbonate and other agents, such as allopurinol or recombinant urate oxidase (rasburicase), should be started immediately to decrease formation and increase the solubility and renal excretion of insoluble urate.[498-500] Recombinant urate oxidase can dramatically decrease uric acid levels within a few hours but, in patients with G6PD deficiency, it can cause methemoglobinemia and life-threatening hemolysis.[501,502]

Patients with WBC counts higher than 100,000/μL have an increased risk for leukostasis. Leukostasis causes intravascular clumping of blasts, leading to sluggish blood flow and subsequent hypoxia, hemorrhage, and infarction of tissue.[331,332,341,342,503] Leukostasis can be life threatening when it occurs in the organs at greatest risk, the brain and lungs. Patients with pulmonary leukostasis present with significant hypoxia and tachypnea, which may progress rapidly to respiratory failure. CNS leukostasis may produce symptoms of confusion, headache, and somnolence and can lead to coma, stroke, and death. Hydration and hydroxyurea are therapies that can be initiated immediately to decrease the blast count. Leukapheresis or exchange transfusion can reduce the number of circulating blasts quickly, although this effect is transient, and therapy with cytoreductive drugs should be started as soon as possible.[503] Routine pheresis for patients with a WBC count higher than 100,000/μL has resulted in lower mortality rates during induction compared with historic controls. In one study, patients who achieved a higher than 30% decrease in total WBCs through pheresis had a higher CR rate than those who achieved less than a 30% decrease.[341,504,505] Other retrospective reviews have shown a decrease in early mortality after leukapheresis but not an improvement in OS. Cytoreductive chemotherapy should be initiated as rapidly as possible because other measures to reduce leukemic blast numbers have only temporary effectiveness.[506,507]

Chemotherapy Complications. High-dose cytarabine is associated with chemical conjunctivitis, and dexamethasone or prednisolone eye drops were traditionally used to prevent this side effect.[508,509] However, recently owing to the unavailability of this steroid formulation, artificial tear products have been effectively substituted. High-dose cytarabine is also associated with neurotoxicity, including seizures and cerebellar dysfunction, which may not be reversible.[510-512] Patients should be monitored with frequent neurologic examinations, and high-dose cytarabine should be immediately discontinued if cerebellar signs develop. Cytarabine may also be associated with an impressive febrile response, which is difficult to distinguish from an infection-related fever.[513,514] AML chemotherapy is associated with significant nausea and vomiting, and aggressive antiemetic regimens should be instituted. However, because of the high risk for fungal infection in these patients, dexamethasone should be avoided as an antiemetic.[515-517] Mucositis is a significant toxicity during AML therapy, predominantly due to anthracyclines, and almost all patients require parenteral pain medication and nutrition. Malnutrition at the time of diagnosis appears to carry a worse prognosis in children with leukemia and, even in those who are well-nourished at diagnosis, weight loss during chemotherapy should be monitored closely, followed by the initiation of parenteral or enteral feedings in those who lose more than 10% of their initial body weight.[518]

Renal toxicity during AML therapy is common and may be caused by a combination of chemotherapy, tumor lysis syndrome, sepsis, or treatment with antibacterial, antifungal, and antiviral agents. A creatinine clearance or glomerular filtration rate should be checked in patients with abnormal creatinine clearance or prolonged use of medications with renal toxicity. For patients with a creatinine clearance lower than 60 mL/min/1.73 m^2, high-dose cytarabine, etoposide, and other renally cleared chemotherapy agents are usually given at reduced dosages. Significant liver toxicity can also be observed during therapy for AML, particularly for regimens containing the humanized anti-CD33 monoclonal antibody, GMTZ. GMTZ has been associated with sinusoidal obstructive syndrome and veno-occlusive disease, most commonly when used as a component of combination therapy or in patients who are heavily pretreated or who have undergone prior HSCT or undergo subsequent HSCT within 3 months of treatment with GMTZ.[519]

AML regimens rely heavily on anthracyclines and their derivatives. The cumulative anthracycline dose in these regimens is often 300 mg/m^2 or higher in daunorubicin equivalents and therefore carries a high risk for cardiac toxicity. Cardiac deaths are one of the top three causes of death in remission for AML patients.[385,425] All patients should undergo cardiac assessment before administration of chemotherapy cycles containing anthracyclines and yearly after chemotherapy is complete, until growth is completed in adulthood. However, recent pharmacogenomic studies suggest that certain genotypes, such as the rs7853758 variant within the SLC28A3 solute transporter, may particularly predispose children to developing anthracycline-induced cardiotoxicity.[520,521] In vitro evidence has suggested that the cardioprotectant dexrazoxane works synergistically, not antagonistically, with anthracyclines against AML blasts, and there is increasing interest in incorporating this medication into AML clinical trials.[522-524] On the current COG AML trial, use of dexrazoxane is permitted at the discretion of the treating physician and data will be collected to determine the impact on both cardiac outcome and secondary malignancy.

Extramedullary Disease

Between 20% and 40% of children with AML have evidence of extramedullary disease at the time of diagnosis.[350,353] The most common manifestations of extramedullary disease are skin infiltrates, soft tissue or bone involvement, gingival infiltration, and CNS involvement. Some patients, particularly infants, may have isolated extramedullary leukemia without other evidence of disease, but bone marrow infiltration invariably occurs in these patients without systemic therapy.

CNS Involvement. CNS involvement is more common in AML patients with high presenting WBC counts, favorable cytogenetic changes—t(9;11), t(8;21), and inv(16)—and children younger than 2 years.[346,420,525] One recent retrospective review of almost 1500 children enrolled on COG AML trials found an incidence of CNS disease (defined as CNS3 status >5 WBCs per high power field with the presence of blasts) of 11%.[526] AML patients with CNS disease at diagnosis have a higher risk for CNS relapse, but they often have a better overall prognosis because CNS disease is more common in the favorable-risk cytogenetic groups, which carry a lower risk for systemic relapse.[525,527] Specific CNS-directed therapy in AML may also be less important than in ALL because several AML chemotherapy agents, including high-dose cytarabine, have excellent CNS penetrance. Cranial radiation was previously used in AML patients as prophylaxis against CNS relapse, but because of concerns about the myriad side effects of CNS radiation, including secondary malignancy, endocrine and growth impairment, and neurocognitive toxicity, later trials attempted to minimize radiation.[528,529] In the BFM-87 study, all patients received intrathecal cytarabine, but the low-risk patients were randomized to additional therapy with cranial radiation or no further CNS treatment. An interim analysis demonstrated no increase in CNS relapse in the group that did not receive cranial radiation, so the radiation arm of the trial was closed early.[349] CNS radiation therapy is no longer routinely part of AML treatment protocols. Intrathecal chemotherapy with cytarabine alone, methotrexate alone, or triple intrathecal therapy with cytarabine, methotrexate, and hydrocortisone have been reported to be effective as CNS treatment and prophylaxis.[420,525,530,531] As prophylaxis for CNS-negative patients, COG study AAML0531 used intrathecal cytarabine alone at the start of each cycle, except for the Capizzi II cycle, which includes 3 g/m^2 of systemic cytarabine. For patients who had CNS disease at diagnosis, twice-weekly intrathecal therapy with cytarabine alone was used until the cerebrospinal fluid was clear, plus an additional two doses, with a minimum of four doses and a maximum of six doses. If more than six doses were required, the patient was taken off study for refractory CNS disease. These guidelines have been maintained on the current AAML1031 study. The SJCRH AML02 trial used a prophylaxis regimen of triple intrathecal chemotherapy with cytarabine, methotrexate, and hydrocortisone given at the start of each cycle but separated by at least 24 hours from systemic cytarabine dosages greater than or equal to 1 g/m^2 to prevent neurotoxicity. Patients with CNS disease at diagnosis receive once-weekly triple intrathecal chemotherapy for four doses. To decrease mucosal toxicity from the methotrexate, all patients receive leucovorin rescue at 24 and 30 hours after the intrathecal administration.

CNS relapse occurs in 2% to 8.8% of patients with AML.[409,420,532] Most AML patients who suffer a CNS relapse will simultaneously or soon thereafter develop a bone marrow relapse. Truly isolated CNS relapse is rare and is associated with age younger than 2 years, hepatosplenomegaly at diagnosis, elevated presenting WBC count, M5 AML, and chromosome 11 abnormalities.[527] For those with a truly isolated CNS relapse, the optimum treatment plan is unclear. There have been survivors reported after treatment with intrathecal chemotherapy alone, combined intrathecal and systemic chemotherapy, radiation therapy, and HSCT.[346,527]

Chloromas. Extramedullary infiltrations of the soft tissue, also known as chloromas, myelosarcomas, or granulocytic sarcomas, occur in 4% to 5% of children with AML.[344,350,533] They may also be documented in patients with CML, MDS, or rarely in ALL and may be initially confused with non-Hodgkin lymphoma.[534] Chloromas most often present simultaneously with AML or shortly before the systemic evidence of disease, but they may be isolated. The prognostic significance of extramedullary disease is not clear. Some groups have reported an unfavorable prognosis associated with chloromas,[382] but others have demonstrated a more favorable outcome.[407,532] Blast cells from patients with chloromas often exhibit the relatively favorable t(8;21).[353,354,535] Most studies from Europe, Saudi Arabia, Japan, and the United States have reported no influence of chloromas on the OS of children with AML,[343,350,382,387,409,536] and a recent review of four COG studies in fact demonstrated that children with orbital or CNS-based chloromas had significantly higher CR rates and OS compared with counterparts without chloromas treated on these same studies.[526] Accordingly, most centers treat patients who have chloromas with standard AML regimens, because there is no consistent evidence supporting more intensive therapy.[350] A beneficial role for radiation therapy in the treatment of chloromas has not been demonstrated.[536] In a CCG trial, patients with chloromas were treated with local irradiation in addition to systemic therapy. There was no difference in EFS or in the incidence of local recurrence compared with the chemotherapy-only regimen. However, chloromas arising in the orbit or CNS may cause loss of vision or cord compression, and emergency radiation therapy as well as chemotherapy is indicated in these situations.[536]

Prognosis

Although historically based exclusively on morphologic subtype, the ability to predict prognosis for patients with AML in the current genomic era derives from a composite of cytogenetic features, molecular subtype, and response to initial chemotherapy as evaluated by MRD. The recent integration of these features on the background of more intensive therapy with better supportive care has enabled a gradual improvement in pediatric AML outcome (Fig. 51-6). Classically, FAB subtype M0, which commonly harbors a complex karyotype, abnormalities of 5 or 7, or trisomy 8, is associated with a poor prognosis.[537] M7 AML (non–Down syndrome), often associated with monosomy 7, carries a poor prognosis.[538-542] M3 AML with the t(15;17) a group previously associated with a dismal prognosis, has emerged as a highly favorable subtype owing to responses with the addition of ATRA and As_2O_3 to chemotherapy regimens.[543-548] Similarly, CBF AML with t(8;21) or inv(16) and normal karyotype AML with either an isolated *CEBPA* or *NPM1* mutations are favorable subtypes.[403,549-551,552] By contrast, *FLT3*-ITD mutations with high allelic ratios are associated with a poor prognosis, as are patients without good-risk molecular features who have significant residual MRD after induction therapy.[401-403,553]

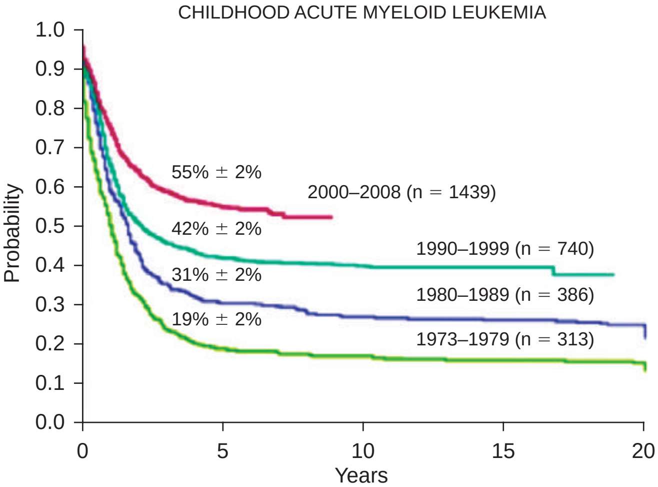

Figure 51-6 Overall survival for pediatric acute myeloid leukemia from 1973 to 2008. *(Modified from Rubnitz J, Inaba H: Childhood acute myeloid leukemia.* Br J Haematol *159:259–287, 2012.)*

Demographic Risk Factors

Age older than 10 years was historically reported to carry a worse prognosis in clinical trials at SJRCH, as well as from the BFM and Japanese groups.[554-556] However, a recent report from the SJCRH AML02 study demonstrated comparable EFS and OS in children as old as age 21 years as in their younger counterparts, although these older children had higher toxic death rates predominantly of infectious etiology.[557] Race and ethnicity play a role in prognosis as well. Patients on CCG2891 who received chemotherapy alone had an OS of 48% for white children versus only 37% for Hispanic children ($P = .016$) and 34% for black children ($P = .007$).[558] On the SJCRH AML97, there was a trend toward inferior outcomes for black compared with white children (hazard ratio, 1.61; 95% confidence interval, 0.76 to 3.42; $P = .22$ with 5-year survival rates of 55.6% vs. 27.3%).[559] In these trials, there was no difference in other prognostic variables between the groups and these patients were hospitalized and received intravenous chemotherapy, received the same supportive care, and had the same compliance rates. Therefore, the observed differences may be attributable to pharmacogenomic differences that affect response to and toxicity from chemotherapy.[538,558] Patients who are overweight (body mass index ≥95th percentile) or underweight (≤10th percentile) also carry a worse prognosis and are less likely to survive and more likely to suffer treatment-related mortality.[560,561]

Cytogenetic Factors

Results of several large multicenter trials have confirmed the correlation between certain cytogenetic abnormalities and clinical outcome and have shown that karyotype in AML represents an independent prognostic variable for attainment of complete response and OS.[310,312,313,316,562] In children and adults, the highest complete response rates and longest survival times have been linked to association with t(8;21) and inv(16) or t(16;16).[403,549-552] These translocations result in modifications to the core-binding complex, a group of proteins that appear to play a vital role in hematopoiesis. AML cells with inv(16) have increased incorporation of cytarabine into nuclear DNA and are more susceptible to cytarabine chemotherapy in vitro.[563] Patients with APL and t(15;17) previously represented a poor-risk group, but, since the advent of ATRA and As_2O_3 therapy (see later), now represent a group with a favorable prognosis.[543-548] Other cytogenetic aberrations have been associated with an unfavorable outcome. These include monosomy 5, del(5q), monosomy 7, abnormalities of 3q, aberrations of 12p, and complex cytogenetic abnormalities.[310,315,564] For pediatric patients with monosomy 7, several studies have shown better OS when HSCT is used as consolidation therapy as opposed to conventional chemotherapy.[541-542] Patients with normal karyotypes have traditionally been grouped together in an intermediate-prognosis group, but now mutations such as the *FLT3*-ITD (poor prognosis) and *NPM1* and *CEBPA* (good prognosis) have been demonstrated to alter prognosis sufficiently to influence the risk assignment of these patients at diagnosis on COG, SJCRH, BFM, and MRC trials. Abnormal karyotypes linked with an intermediate prognosis include del(7q), 11q23 translocations, +21, +8, +22, and del(9q).[310,565] Other karyotypes such as t(6;9)(p23;q34), t(8;16)(p11;p13), and t(16;21)(q24;q22) are uncommon but appear associated with a poorer prognosis.[557,566-568] While more studies with large numbers of patients undergoing cytogenetic evaluation are completed, certain groups of karyotype aberrations are showing heterogeneity in their prognostic significance. For example, all 11q23 translocations were previously grouped together in the intermediate- to poor-prognosis category. However, studies have shown that the 11q23 aberration may be subdivided into groups of lesser and greater prognostic risk.[569] Patients with the t(9;11)(p22;q23) have been found in some studies to have a longer EFS and OS than patients with other 11q23 translocations.[247,312,314,315,565,562] However, this was not found to be true in a recent review of outcome on MRC10 and 12 trials.[366] As new therapeutic agents are developed that target the specific molecular aberrations identified by cytogenetic analysis, accurate detection of these abnormalities becomes even more important.[565]

Molecular Genetic Factors

Analysis of molecular genetics is emerging as an invaluable tool in prognostic determination for patients with AML, as well as for providing insight into the pathogenesis of AML and elucidating possibilities for targeted therapy.[136] *RAS* mutations have been identified in pediatric AML patients, with *NRAS* mutations in 10% to 15% and *KRAS* mutations in 3% of patients.[570] *HRAS* mutations are rare in AML. In both adults and children these mutations are associated with favorable-risk AML. In adults, the association is with CBF leukemias and, in particular, inv(16).[570,571] Although some pediatric studies have also found a link between CBF AML and *NRAS* mutations,[570,571] others have found a distinct absence of *NRAS* with inv(16) and a unique correlation of *NRAS* and *NPM* mutations not seen in adult AML.[157] Independently, however, *NRAS* mutations have no significant impact on prognosis.[153,572,570,573-576] Patients had similar 5-year EFS and OS, although patients with *NRAS* mutations were associated with increased treatment-related mortality on one study.[157] *KIT* mutations have been identified in 11.3% of pediatric AML patients,[570] predominantly in the CBF leukemias, ranging from 17% to 41% of patients.[178,577-580] The role of *KIT* mutations in prognosis has been unclear: in some series, the *KIT* mutations do not seem to have prognostic significance, in others, *KIT* mutations have been shown to confer worse prognosis in patients with t(8;21) but not in patients with inv(16) and, in still other trials, *KIT* mutations confer a worse prognosis in all subsets of CBF leukemias.[570,571,581,582] However, a recent review of more than 200 children with CBF AML enrolled on four COG AML trials concluded that *KIT* mutations do not alter prognosis.[178] Owing to their good outcome with chemotherapy alone, patients with CBF AML are currently nonrandomly assigned to chemotherapy without HSCT in CR1 even if a matched family donor is available. Based on these recent data, on current COG trials the presence of a *KIT* mutation does not alter risk stratification. This is in contrast to adult data which show that *KIT* mutations appear to confer an inferior outcome.[583-585] These prognostic differences in adult versus pediatric CBF AML may reflect more aggressive therapy in children and, potentially, an earlier cell of origin in the adult disease that contributes to increased resistance to therapy.

As noted, *FLT3* mutations include ITDs in the juxtamembrane domain and point mutations in the activation loop (ALM). *FLT3*-ITDs have a worse prognosis, particularly when present in a high allelic ratio (>0.4),[174,586,587-590] whereas *FLT3*-ALMs seem to have no impact on prognosis.[174,586,589] Partial tandem duplications of the *MLL* gene have also been reported in 13% of pediatric AML patients and are associated with a worse prognosis in adult and pediatric patients.[228,586,591,592] Frameshift mutations in *NPM1* lead to cytoplasmic localization of nucleophosmin and have been identified in 6% to 8% of all children with AML and 25% to 30% of pediatric AML patients with normal cytogenetics.[277,278] When identified as an isolated mutation in adults and children, it is associated with improved prognosis, but when found in conjunction with an *FLT3*-ITD, the poor prognostic impact of the *FLT*-ITD prevails.[277,278,593-595] With contemporary chemotherapy, children with AML with a normal karyotype and isolated *NPM1* mutation have outcomes in keeping with CBF leukemia with OS greater than 80%; thus these children have been assigned to the low-risk arm on the current COG trial[557] (R. Aplenc, personal communication, June 2011). *PTPN11* mutations are found in only 4% of pediatric patients with AML (4%), and 18% to 36% of the *PTPN11* mutations are seen in M5 AML. In pediatrics, this mutation does not appear to have prognostic importance.[142,596] The Wilms tumor gene *(WT1)* is aberrantly expressed in AML; in adults, high expression levels of WT1 at diagnosis have been associated with a poor prognosis in many studies.[597-602] In pediatric patients, however, the available data have been contradictory. One small study of 47 patients has shown that low levels of WT1 at diagnosis are associated with good outcome,[603] whereas another small study of 41 patients has shown that high levels of WT1 are more commonly seen in association with the t(8;21) and inv(16) favorable prognosis cytogenetic findings, and therefore associated with a better prognosis.[604] Hollink and colleagues found an association between *WT1* mutations and an inferior outcome.[282] More recently, a large study performed by the COG identifying 70 patients with *WT1* mutations found that although there was significant overlap of the *WT1* mutation with either CBF or *FLT3*-ITD, independently, *WT1* mutations did not influence prognosis.[281] Interestingly, 28% of pediatric AML patients harbor a minor single nucleotide polymorphism (SNP) in exon 7 of *WT1* (rs16754) that was found to result in an improved 5-year OS (62% vs. 44%) for patients treated on CCG 2961 compared with those with leukemic expression of the major *WT1* allele.[289] Levels of expression of wild-type WT1 may also influence prognosis. However, at present, *WT1* mutational status, presence of the minor SNP, and wild-type expression levels continue to be studied but are not being used to make treatment decisions. In addition to its role as a partner in the t(8;21) translocation, *RUNX1* may also be mutated in approximately 5% of pediatric AML patients, specifically with point mutations in exons 3 and 8. Although typically associated with AML secondary to MDS, in de novo AML these patients had less organomegaly, a higher incidence of chloromas, and a trend toward improved outcome with modern intensive AML therapy.[605] However, *RUNX1* mutations are not currently used for risk stratification.

CEBPA mutations have been found to be an independent prognostic marker conferring a good outcome in both pediatric and adult AML and, similar to that seen for CBF AML, at least in children.[279] Interestingly, pediatric patients with AML and *CEBPA* mutations tend to be older (age >10 years) and predominantly have a normal karyotype with an absence of other good- or poor-risk molecular abnormalities. Furthermore, patients with *CEBPA* mutations did not benefit from HSCT in first remission. Thus, in current studies, presence of a *CEBPA* mutation classifies a patient as low risk. Recent next-generation sequencing–based studies have revealed frequent mutations in the DNA methyltransferase gene, *DNMT3A,* the gene coding for the demethylating enzyme, *TET2,* and the genes *IDH1* and *IDH2*, which code for proteins in the Krebs cycle. *DNMT3A* mutations are generally associated with a poor outcome and contribute to a worse prognosis when combined with *FLT3* ITD. *TET2* mutations are similarly associated with a poor prognosis, with or without corresponding *FLT3* abnormalities. By contrast, *IDH1/IDH2* mutations appear to be more positive prognostic features.[606,607] However, these abnormalities are generally rare in pediatric AML[608]; thus their impact cannot be easily determined, and at this time they have been excluded from any current pediatric AML risk stratification schemas.

Minimal Residual Disease

Early response to treatment, as assessed by MRD in the bone marrow and/or the peripheral blood after induction therapy, has been shown to be an independent and powerful prognostic factor in pediatric leukemia. MRD can be detected by molecular means such as PCR assay, which is beneficial for the monitoring of leukemias with fusion genes or recurrent mutations. Alternatively, the use of multiparameter flow cytometry (MPFC) is more universally applicable, but it may be user dependent and vary significantly based on technical aspects, threshold levels, and timing of evaluation.

PCR-based MRD evaluation requires that a cytogenetic abnormality or mutation present at diagnosis will be predictive of relapse or refractory disease. In CBF AML, persistence of the *AML1-ETO* t(8:21) or *CBFB-MYH11* inv(16) transcripts long after completion of therapy has challenged the value of following these lesions either during or after completion of therapy.[557,609] However, a recent adult study[610] has suggested that at least in AML with inv(16), PCR analysis may have more predictive power. Negative bone marrow results of PCR assay for the *CBFB-MYH11* transcript (<10 detectable copies per cell) early in consolidation with two subsequent negative PCR evaluations either in the bone marrow or peripheral blood later in consolidation and within 3 months of completing therapy were highly predictive of remaining in CR, with a high correlation between bone marrow and peripheral blood measurements during surveillance. In APL and CML (see later), levels of *PML-RARA* or *BCR-ABL* transcripts have been found to be extremely valuable for monitoring, although the site of monitoring has been somewhat controversial. Standardized monitoring for *BCR-ABL* levels in the peripheral blood is now accepted as the standard of care in CML, whereas the recently closed COG trial in APL has mandated bone marrow evaluations during maintenance and subsequent follow-up. A number of adult and pediatric studies have examined following *FLT3, CEBPA, NPM1, MLL* rearrangements/PTDs, or *WT1* mutations in those patients harboring these abnormalities at diagnosis.[609,611-617] However, the utility of any of these mutations as a molecular MRD marker remains uncertain owing to stability of the mutation (*FLT3*-ITD) or normal background levels *(WT1)*. Thus, although their presence at diagnosis may be indicative of response, persistence of these lesions is not being routinely used to evaluate disease response in pediatric AML.

By contrast, use of MRD by MPFC has proven to be a more broadly applicable component of risk stratification in both pediatric ALL[618] and AML.[403,404,619] Particularly in the large subset of intermediate-risk AML, MRD has allowed the distinction of standard- and high-risk groups, whereas the use of morphology alone proved insufficient.[355] The ability of MPFC MRD measurement to contribute to the evaluation of early treatment response and improve prognostic evaluation in pediatric AML was demonstrated for CCG 2961. OS for patients in morphologic remission after induction I was 41% if MRD was positive, compared with 69% for those who were MRD negative.[404] A strong impact of MRD was also apparent in AML patients who were in morphologic remission at the end of induction I on the recent AAML03P1 study. The 46 MRD-positive patients of the 188 patients deemed

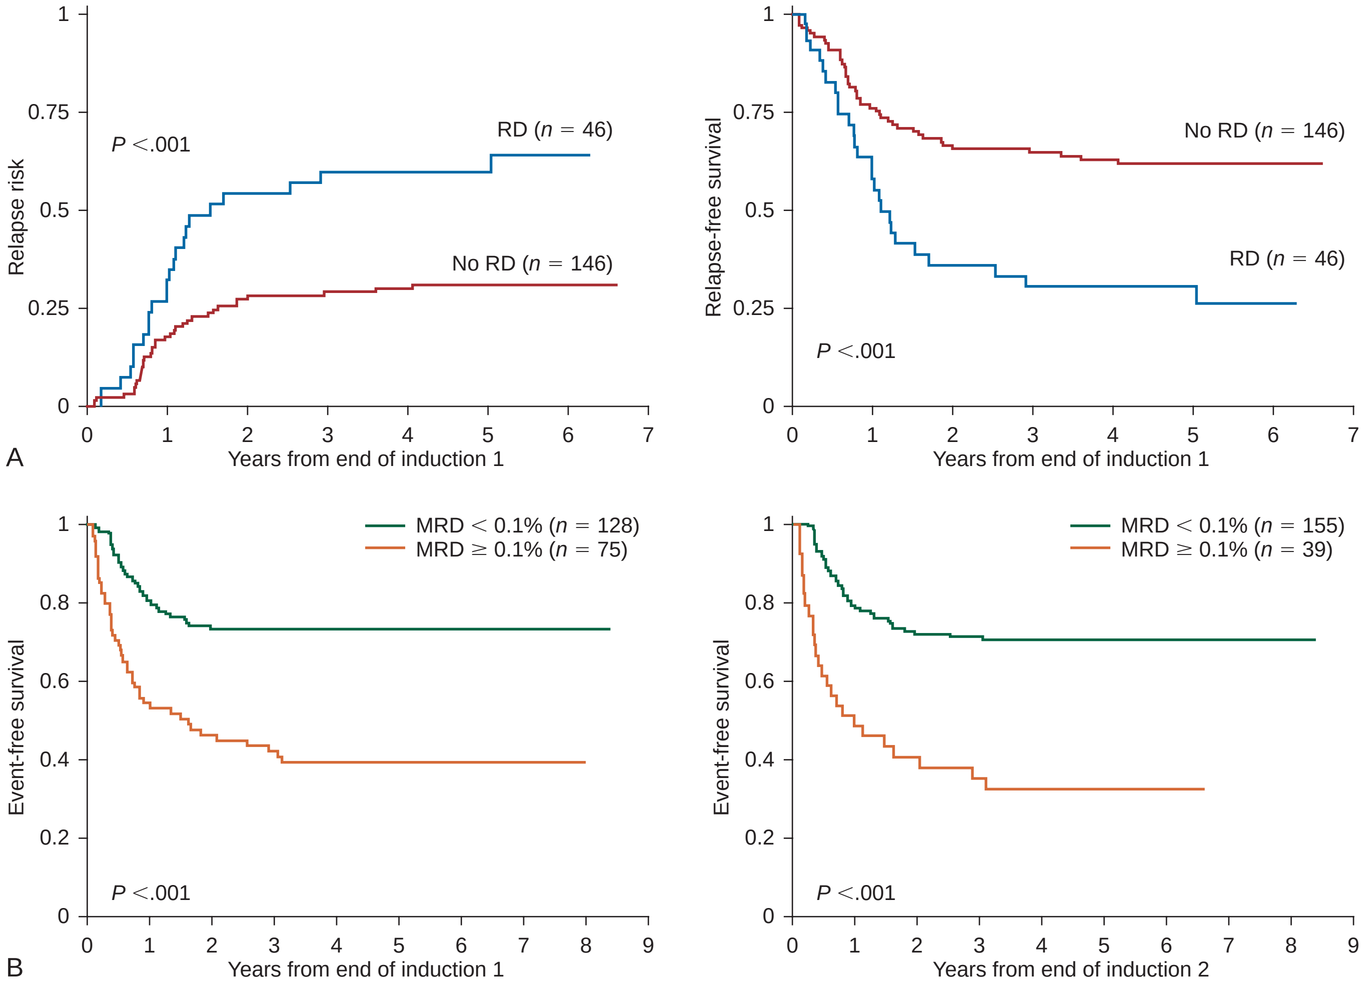

Figure 51-7 **A,** Minimal residual disease *(MRD)* by multiparameter flow cytometry (MPFC) can predict outcome for children with acute myeloid leukemia found to be in morphologic remission (*RD,* residual disease detected by MPFC). **B,** MRD levels less than 0.1% appear most predictive of event-free survival after induction therapy. *(Modified from Loken MR, Alonzo TA, Pardo L, et al: Residual disease detected by multidimensional flow cytometry signifies high relapse risk in patients with de novo acute myeloid leukemia: a report from the Children's Oncology Group.* Blood *120:1581–1588, 2012; and Inaba H, Coustan-Smith E, Cao X, et al: Comparative analysis of different approaches to measure treatment responses in acute myeloid leukemia.* J Clin Oncol *30:3625–3632, 2012.)*

in CR showed an increase in relapse risk (RR) at 3 years (60%, *P* <.001) and lower DFS (30%, *P* <.001) and OS (56%, *P* = .002) compared with those who were MRD negative (3-year RR, 29%; DFS, 65%; OS, 80%) (Fig. 51-7, *A*).[355] Not only did this study demonstrate the adverse prognostic value of positive MRD compared with morphology alone but, conversely, showed that 26% of patients deemed as having disease based on morphologic bone marrow evaluation were in fact MRD negative and had a good outcome.[355] Similar findings were identified by the SJCRH, confirming that recovering normal marrow blasts and leukemic myeloblasts can be challenging to distinguish morphologically even by the most experienced hematopathologist.[609] Multivariate analyses on COG and SJCRH studies confirmed positive MRD as an independent adverse prognostic factor, although the SJCRH study found that this was only significant for MRD levels greater than 1% after induction I, or greater than 0.1% after induction II,[403] whereas this distinction was not specifically identified in the COG studies. Subsequent analysis by the SJCRH demonstrated that an MRD threshold of 0.1% was independently predictive of outcome both after induction I and induction II (see Fig. 51-7, *B*).[609] The impact of MRD was independently confirmed in recent MRC and Dutch trials.[619] Furthermore, COG studies found that MRD levels held their prognostic significance in normal karyotype AML. Based on these data, the COG has used MRD by MPFC to eliminate the intermediate-risk group of patients without prognostic cytogenetic or molecular features. Those patients with residual MRD at a threshold of 0.1% after the first induction cycle are deemed at high risk and relegated to more intensive therapy, whereas those with MRD levels below 0.1% are allocated to a low-risk study arm.

Relapsed or Refractory Disease

The prognosis is grave for children with disease refractory to induction chemotherapy or who have a disease relapse. Although 80% to 90% of pediatric patients with AML will achieve remission, 30% to 40% will later recur, and the OS remains only 40% to 60%.[363,530,531,538,620-624] The bone marrow is the most common site of relapse in AML, and isolated CNS relapse is an uncommon finding, but isolated CNS relapse has been associated with prior CNS involvement.[386,527,625]

Prognosis in Relapsed or Refractory Disease

A durable remission is less likely to be achieved and maintained in patients with relapsed or refractory AML than in patients with newly diagnosed AML, but the salvage rate in these patients has improved in recent years.[538,624,626] The single most important prognostic indicator after relapse is duration of first remission, with less than 1 year to relapse carrying an OS rate of 0% to 21% and longer than 1 year to relapse carrying an OS rate of 33% to 62%.[386,539,624,627-631] Other characteristics that have been associated with better prognosis after relapse are male gender, good-risk cytogenetic features of t(8;21) and inv(16), chemotherapy alone without HSCT as consolidation during first CR, and the use of HSCT as part of relapse therapy. The characteristics associated with worse prognosis after relapse are early recurrence, M5 or M7 morphology, poor-risk cytogenetics, and HSCT during first CR.
